Boosting with Early Stopping: Convergence and Consistency

Tong Zhang* Bin Yu†

Abstract

Boosting is one of the most significant advances in machine learning for classification and regression. In its original and computationally flexible version, boosting seeks to minimize empirically a loss function in a greedy fashion. The resulted estimator takes an additive function form and is built iteratively by applying a base estimator (or learner) to updated samples depending on the previous iterations. An unusual regularization technique, early stopping, is employed based on CV or a test set.

This paper studies numerical convergence, consistency, and statistical rates of convergence of boosting with early stopping, when it is carried out over the linear span of a family of basis functions. For general loss functions, we prove the convergence of boosting's greedy optimization to the infinimum of the loss function over the linear span. Using the numerical convergence result, we find early stopping strategies under which boosting is shown to be consistent based on iid samples, and we obtain bounds on the rates of convergence for boosting estimators. Simulation studies are also presented to illustrate the relevance of our theoretical results for providing insights to practical aspects of boosting.

As a side product, these results also reveal the importance of restricting the greedy search step sizes, as known in practice through the works of Friedman and others. Moreover, our results lead to a rigorous proof that for a linearly separable problem, AdaBoost with $\epsilon \to 0$ stepsize becomes an L^1-margin maximizer when left to run to convergence.

1 Introduction

In this paper we consider boosting algorithms for classification and regression. These algorithms present one of the major progresses in machine learning. In their original version, the computational aspect is explicitly specified as part of the estimator/algorithm. That is, the empirical minimization of an appropriate loss function is carried out in a greedy fashion, which means that at each step, a basis function that leads to the largest reduction of empirical risk is added into the estimator. This specification distinguishes boosting from other statistical procedures which are defined by an empirical minimization of a loss function without the numerical optimization details.

Boosting algorithms construct composite estimators using often simple base estimators through the greedy fitting procedure. An unusual regularization technique, early stopping, is employed based on CV or a test set. This family of algorithms has been known as the stage-wise fitting

of *additive models* in the statistics literature [18, 17]. For the squared loss function, they were often mentioned in the signal processing community as *matching pursuit* [29]. More recently, it was noticed that the Adaboost method proposed in the Machine Learning community [13] could also be regarded as stage-wise fitting of additive models under the exponential loss function [7, 8, 15, 31, 34]. In this paper, we use the term *boosting* to indicate a greedy stage-wise procedure to minimize a certain loss function empirically. The abstract formulation will be presented in Section 2.

Boosting procedures have drawn much attention in the machine learning community as well as in the statistics community, due to their superior empirical performance for classification problems. In fact boosted decision trees are generally regarded as the best off-the-shelf classification algorithms we have today. In spite of the significant practical interests in boosting, a number of theoretical issues have not been fully addressed in the literature. In this paper, we hope to fill some gaps by addressing three basic issues regarding boosting: its numerical convergence when the greedy iteration increases in Section 4.1, its consistency (after early stopping) when the training sample size gets large in Section 3.3 and Section 5.2, and bounds on the rate of convergence for boosting estimators in Section 3.3 and Section 5.3.

It is now well-known that boosting forever can overfit the data (for example, see [16, 19]). Therefore in order to achieve consistency, it is necessary to stop the boosting procedure early (but not too early) to avoid overfitting. In the early stopping framework, the consistency of boosting-procedures have been considered by Jiang for the exponential loss [19] boosting (but the consistency is in terms of the classification loss) and Bühlmann under the squared loss [10] for tree-type base classifiers. Jiang's approach also requires some smoothness conditions on the underlying distribution, and is non-constructive (hence does not lead to an implementable early-stopping strategy). In Section 3.3 and Section 5.2, we present an early-stopping strategy for general loss functions that guarantees consistency.

A different method of achieving consistency (and obtaining rate of convergence results) is through restricting the weights of the composite estimator using the 1-norm of its coefficients (with respect to the basis functions). For example this point of view is taken up in [28, 5, 30]. In this framework, early-stopping is not necessary since the degree of over-fitting or regularization is controlled by the 1-norm of the weights of the composite estimator. Although this approach simplifies the theoretical analysis, it also introduces an additional control quantity which needs to be adjusted based on the data. Therefore in order to select an optimal regularization parameter, one has to solve many different optimization problems, each with a regularization parameter. Moreover, if there are an infinitely (or extremely large) number of basis functions, then it is not possible to solve the associated 1-norm regularization problem. Note that in this case, greedy boosting (with approximate optimization) can still be applied.

A question related to consistency and rate of convergence is the convergence of boosting procedure as an optimization method. This is clearly one of the most fundamental theoretical issues for boosting algorithms. Previous studies have been focused on special loss functions. Specifically, Mallat and Zhang proved the convergence of matching pursuit in [29], which was then used in [10] to study consistency; in [9], Breiman obtained an infinite-sample convergence result of boosting with the exponential loss function for ± 1-trees (under some smoothness assumptions on the underlying

distribution), and the result was used by Jiang to study the consistency of Adaboost. In [12], a Bregman divergence based analysis was given. A convergence result was also obtained in [31] for a gradient descent version of boosting.

None of these studies provide any information on the numerical speed of convergence for the optimization. The question of numerical speed of convergence has been studied when one works with the 1-norm regularized version of boosting where we assume that the optimization is performed in the convex hull of the basis functions. Specifically, for function estimation under the least squares loss, the convergence of greedy algorithm in convex hull was studied in [20, 1, 25]. For general loss functions, the convergence of greedy algorithms (again, the optimization is restricted to the convex hull) was recently studied in [37]. In this paper, we apply the same underlying idea to the standard boosting procedure where we do not limit the optimization to the convex hull of the basis functions. The resulting bound provides information on the speed of convergence for the optimization. An interesting observation of our analysis is the important role of small step-size in the convergence of boosting procedures. This provides some theoretical justification for Friedman's empirical observation [14] that using small step-sizes almost always helps in boosting procedures.

Moreover, the combination of numerical convergence results with modern empirical process bounds (based on Rademacher complexity) provides a way to derive bounds on the convergence rates of early-stopped boosting procedures. These results can be found in Section 3.3 and Section 5.3. Section 6 contains a simulation study to show the usefulness of the insights from our theoretical analyses in practical implementations of Boosting. The proofs of the two main results in the numerical convergence section (Section 4.1) are deferred to Appendix B. Appendix C discusses relaxations of the restricted stepsize condition used for earlier results, and Appendix D uses the numerical convergence results to give a rigorous proof of the fact that for separable problems, AdaBoost with small stepsize becomes an L_1 margin maximizer at its limit (see [17]).

2 Abstract Boosting Procedure

We now describe the basics to define the boosting procedure that we will analyze in this paper. A similar set-up can be found in [31]. The main difference is that they use a gradient descent rule in their boosting procedure while here we use approximate minimization.

Let S be a set of real-valued functions, and define

$$\mathrm{span}(S) = \left\{ \sum_{j=1}^{m} w^j f^j : f^j \in S, w^j \in R, m \in Z^+ \right\},$$

which forms a linear function space. For all $f \in \mathrm{span}(S)$, we can define its 1-norm with respect to the basis S as:

$$\|f\|_1 = \inf \left\{ \|w\|_1; f = \sum_{j=1}^{m} w^j f^j : f^j \in S, m \in Z^+ \right\}. \quad (1)$$

We want to find a function $\bar{f} \in \mathrm{span}(S)$ that approximately solves the following optimization

problem:

$$\inf_{f \in \mathrm{span}(S)} A(f), \tag{2}$$

where A is a convex function of f defined on $\mathrm{span}(S)$. Note that the optimal value may not be achieved by any $f \in \mathrm{span}(S)$, and for certain formulations (such as AdaBoost) it is possible that the optimal value is not finite. Both cases are still covered by our results, however.

The abstract form of greedy-boosting procedure (with restricted step size) considered in this paper is given by the following algorithm:

Algorithm 2.1 *(Greedy Boosting)*

Pick $f_0 \in \mathrm{span}(S)$
for $k = 0, 1, 2, \ldots$
  Select a closed subset $\Lambda_k \subset R$ such that $0 \in \Lambda_k$ and $\Lambda_k = -\Lambda_k$
  Find $\bar{\alpha}_k \in \Lambda_k$ and $\bar{g}_k \in S$ to approximately minimize the function:
    $(\alpha_k, g_k) \to A(f_k + \alpha_k g_k) \qquad (*)$
  Let $f_{k+1} = f_k + \bar{\alpha}_k \bar{g}_k$
end

Remark 2.1 *The approximate minimization of* $(*)$ *in Algorithm 2.1 should be interpreted as finding* $\bar{\alpha}_k \in \Lambda_k$ *and* $\bar{g}_k \in S$ *such that*

$$A(f_k + \bar{\alpha}_k \bar{g}_k) \leq \inf_{\alpha_k \in \Lambda_k, g_k \in S} A(f_k + \alpha_k g_k) + \epsilon_k, \tag{3}$$

where $\epsilon_k \geq 0$ *is a sequence of non-negative numbers that converges to zero.*

Remark 2.2 *The requirement that* $0 \in \Lambda_k$ *is not crucial in our analysis. It is used as a convenient assumption in the proof of Lemma 4.1 to simplify the conditions. Our convergence analysis allows the choice of* Λ_k *to depend on the previous steps of the algorithm. However, the most interesting* Λ_k *for the purpose of this paper will be independent of previous steps of the algorithm:*

- $\Lambda_k = R$
- $\sup \Lambda_k = \tilde{h}_k$ *where* $\tilde{h}_k \geq 0$ *and* $\tilde{h}_k \to 0$.

As we will see later, the restriction of α_k *to the subset* $\Lambda_k \subset R$ *is useful in the convergence analysis.*

As we shall see later, the step size $\bar{\alpha}_k$ plays an important role in our analysis. A particular interesting case is to restrict the step-size explicitly. That is, we assume that the starting point f_0, as well as quantities ϵ_k and Λ_k in (3), are sample-independent, and $h_k = \sup \Lambda_k$ satisfies the following conditions:

$$\sum_{j=0}^{\infty} h_j = \infty, \qquad \sum_{j=0}^{\infty} h_j^2 < \infty. \tag{4}$$

The reason for this condition will become clear in the numerical convergence analysis of Section 4.1.

3 Assumptions and Main Statistical Results

The purpose of this section is to state assumptions needed for the analyses to follow, as well as the main statistical results. There are two main aspects of our analysis. The first aspect is for the numerical convergence of the boosting algorithm as the number of iterations increases, and the second aspect is for the statistical convergence of the resulting boosting estimator, so as to avoid overfitting. We list respective assumptions separately. The statistical consistency result can be obtained by combining these two aspects.

3.1 Assumption for the Numerical Convergence Analysis

For all $f \in \text{span}(S)$ and $g \in S$, we define a real-valued function $A_{f,g}(\cdot)$ as:

$$A_{f,g}(h) = A(f + hg).$$

Definition 3.1 *Let $A(f)$ be a function of f defined on $\text{span}(S)$. Denote by $\text{span}(S)'$ the dual space of $\text{span}(S)$ (that is, the space of real valued linear functionals on $\text{span}(S)$). We say that A is differentiable with gradient $\nabla A \in \text{span}(S)'$ if it satisfies the following Fréchet-like differentiability condition for all $f, g \in \text{span}(S)$:*

$$\lim_{h \to 0} \frac{1}{h}(A(f + hg) - A(f)) = \nabla A(f)^T g,$$

where $\nabla A(f)^T g$ denotes the value of linear functional $\nabla A(f)$ at g. Note that we adopt the notation $f^T g$ from linear algebra, where it is just the scalar product of the two vectors.

For reference, we shall state the following assumption which is required in our analysis:

Assumption 3.1 *Let $A(f)$ be a convex function of f defined on $\text{span}(S)$, which satisfies the following conditions*

1. *The functional A is differentiable with gradient ∇A.*
2. *For all $f \in \text{span}(S)$ and $g \in S$, the real-valued function $A_{f,g}$ is second order differentiable (as a function of h) and the second derivative satisfies:*

$$A''_{f,g}(0) \leq M(\|f\|_1), \tag{5}$$

where $M(\cdot)$ is a non-decreasing real-valued function.

Remark 3.1 *A more general form of (5) is $A''_{f,g}(0) \leq \ell(g)M(\|f\|_1)$, where $\ell(g)$ is an appropriate scaling factor of g. For example, in the examples given below, $\ell(g)$ can be measured by $\sup_x |g(x)|$ or $E_X g(X)^2$. In (5), we assume that functions in S are properly scaled so that $\ell(g) \leq 1$. This is for notation convenience only. With more complicated notation, techniques developed in this paper can also handle the general case directly without any normalization assumption of the basis functions.*

The function $M(\cdot)$ will appear in the convergence analysis in Section 4.1. Although our analysis can handle unbounded $M(\cdot)$, the most interesting boosting examples have bounded $M(\cdot)$ (as we will show shortly). In this case, we will also use M to denote a real-valued upper bound of $\sup_a M(a)$.

For statistical estimation problems such as classification and regression with a covariate or predictor variable X and a real response variable Y having a joint distribution, we are interested in the following form of $A(f)$ in (2):

$$A(f) = \psi(E_{X,Y}\phi(f(X), Y)), \tag{6}$$

where $\phi(\cdot,\cdot)$ is a loss function that is convex in its first argument and ψ is a monotonic increasing auxiliary function which is introduced so that $A(f)$ is convex and $M(\cdot)$ behaves nicely (e.g. bounded). We note that the introduction of ψ is for proving numerical convergence results using our proof techniques, which are needed for proving statistical consistency of boosting with early stopping. However ψ is not necessary for the actual implementation of the boosting procedure. Clearly the minimizer of (6) that solves (2) does not depend on the choice of ψ. Moreover the behavior of Algorithm 2.1 is not affected by the choice of ψ as long as ϵ_k in (3) is appropriately redefined. We may thus always take $\psi(u) = u$, but choosing other auxiliary functions can be convenient for certain problems in our analysis since the resulted formulation has bounded $M(\cdot)$ function (see examples given below). We have also used $E_{X,Y}$ to indicate the expectation with respect to the joint distribution of (X, Y).

When not explicitly specified, $E_{X,Y}$ can either denote the expectation with respect to the underlying population or with respect to the empirical samples. This makes no difference as far as our convergence analysis in Section 4.1 is concerned. When it is necessary to distinguish an empirical quantity from its population counterpart, we shall denote the former by a hat above the corresponding quantity. For example, $\hat{E}$ denotes the expectation with respect to the empirical samples, and $\hat{A}$ is the function in (6) with $E_{X,Y}$ replaced by $\hat{E}_{X,Y}$. This distinction will become necessary in the uniform convergence analysis of Section 4.2.

An important application of boosting is binary classification. In this case, it is very natural for us to use a set of basis functions that satisfy the following conditions:

$$\sup_{g\in S,x} |g(x)| \leq 1, \qquad y = \pm 1. \tag{7}$$

For certain loss functions (such as least squares), this condition can be relaxed. In the classification literature, $\phi(f, y)$ usually has a form $\phi(fy)$.

Commonly used loss functions are listed in Appendix A. They show that for a typical boosting loss function ϕ, there exists a constant M such that $\sup_a M(a) \leq M$.

3.2 Assumption for the Statistical Convergence Analysis

In classification or regression problems with a covariate or predictor variable X on R^d and a real response variable Y, we observe m iid samples $Z_1^m = \{(X_1, Y_1), \ldots, (X_m, Y_m)\}$ from an unknown underlying distribution D. Consider a loss function $\phi(f, y)$ and define $Q(f)$ (true risk) and $\hat{Q}(f)$

(empirical risk) as:

$$Q(f) = E_D \phi(f(X), Y), \quad \hat{Q}(f) = \hat{E}\phi(f(X), Y) = \frac{1}{m}\sum_{i=1}^{m} \phi(f(X_i), Y_i), \tag{8}$$

where E_D is the expectation over the unknown true joint distribution D of (X, Y) (and it was denoted by $E_{X,Y}$ previously); $\hat{E}$ is the empirical expectation based on the sample Z_1^m.

Boosting estimators are constructed by applying Algorithm 2.1 with respect to the empirical expectation $\hat{E}$ with a set S of real-valued basis functions $g(x)$. We use $\hat{A}(f)$ to denote the empirical objective function:

$$\hat{A}(f) = \psi(\hat{Q}(f)) = \psi(\hat{E}\phi(f(X), Y)).$$

Similarly, quantities f_k, α_k and g_k in Algorithm 2.1 will be replaced by $\hat{f}_k$, $\hat{\alpha}_f$, and $\hat{g}_k$ respectively.

Techniques from the modern empirical process theory can be used to analyze the statistical convergence of boosting estimator with finite sample. In particular, we use the concept of Rademacher complexity, which is given by the following definition.

Definition 3.2 *Let $G = \{g(x, y)\}$ be a set of functions of input (x, y). Let $\{\sigma_i\}_{i=1}^m$ be a sequence of binary random variables such that $\sigma_i = \pm 1$ with probability $1/2$. The (one-sided) sample-dependent* Rademacher complexity *of G is given by*

$$R_m(G, Z_1^m) = E_\sigma \sup_{g \in G} \frac{1}{m}\sum_{i=1}^{m} \sigma_i g(X_i, Y_i),$$

and the expected Rademacher complexity of G is denoted by

$$R_m(G) = E_{Z_1^m} R_m(G, Z_1^m).$$

The Rademacher complexity approach for analyzing boosting algorithms appeared first in [21], and has been used by various people to analyze learning problems including boosting, for example, see [3, 2, 4, 6, 30]. The analysis using Rademacher complexity as defined above can be applied both to regression and to classification. However for notational simplicity, we focus only on boosting methods for classification, where we impose the following assumption. This assumption is not essential to our analysis, but it simplifies the calculations and some of the final conditions.

Assumption 3.2 *We consider the following form of ϕ in (8): $\phi(f, y) = \phi(fy)$ with a convex function $\phi(a) : R \to R$ such that $\phi(-a) > \phi(a)$ for all $a > 0$. Moreover, we assume that*

- *Condition (7) holds.*
- *S in Algorithm 2.1 is closed under negation (that is, $f \in S \to -f \in S$).*
- *There exists a finite Lipschitz constant $\gamma_\phi(\beta)$ of ϕ in $[-\beta, \beta]$:*

$$\forall |f_1|, |f_2| \le \beta : |\phi(f_1) - \phi(f_2)| \le \gamma_\phi(\beta)|f_1 - f_2|.$$

The Lipschitz condition of a loss function is usually easy to estimate. For reference, we list γ_ϕ for loss functions considered in Appendix A.

- Logistic regression $\phi(f) = \ln(1 + \exp(-f))$: $\gamma_\phi(\beta) \leq 1$.
- Exponential $\phi(f) = \exp(-f)$: $\gamma_\phi(\beta) \leq \exp(\beta)$.
- Least squares $\phi(f) = (f-1)^2$: $\gamma_\phi(\beta) \leq 2(\beta+1)$.
- Modified least squares $\phi(f) = \max(1-f, 0)^2$: $\gamma_\phi(\beta) \leq 2(\beta+1)$.
- p-norm $\phi(f) = |f-1|^p$ $(p \geq 2)$: $\gamma_\phi(\beta) \leq p(\beta+1)^{p-1}$.

3.3 Main Statistical Results

We may now state the main statistical results based on the assumptions and definitions given earlier. The following theorem gives conditions for our boosting algorithm so that the consistency can be achieved in the large sample limit. The proof is deferred to Section 5.2, with some auxiliary results.

Theorem 3.1 *Under Assumption 3.2, and let ϕ be one of the loss functions considered in Appendix A. Assume further that in Algorithm 2.1, we choose quantities f_0, ϵ_k, and Λ_k to be independent of the sample Z_1^m, such that $\sum_{j=0}^{\infty} \epsilon_j < \infty$, and $h_k = \sup \Lambda_k$ satisfies (4).*

Consider two sequences of sample independent numbers k_m and β_m such that $\lim_{m\to\infty} k_m = \infty$ and $\lim_{m\to\infty} \gamma_\phi(\beta_m)\beta_m R_m(S) = 0$. Then as long as we stop Algorithm 2.1 at a step $\hat{k}$ based on Z_1^m such that $\hat{k} \geq k_m$ and $\|\hat{f}_{\hat{k}}\|_1 \leq \beta_m$, we have the following consistency result:

$$\lim_{m\to\infty} E_{Z_1^m} Q(\hat{f}_{\hat{k}}) = \inf_{f \in \mathrm{span}(S)} Q(f).$$

Remark 3.2 *The choice of (k_m, β_m) in the above theorem should not be void in the sense that for all sample Z_1^m, it should be possible to stop Algorithm 2.1 at a point such that the conditions $\hat{k} \geq k_m$ and $\|\hat{f}_{\hat{k}}\|_1 \leq \beta_m$ are satisfied.*

In particular, if $\lim_{m\to\infty} R_m(S) = 0$, then we can always find $k_m \leq k'_m$ such that $k_m \to \infty$ and $\gamma_\phi(\beta_m)\beta_m R_m(S) \to 0$ with $\beta_m = \|f_0\|_1 + \sum_{j=0}^{k'_m} h_j$. This choice of (k_m, β_m) is valid as we can stop the algorithm at any $\hat{k} \in [k_m, k'_m]$.

Similar to the consistency result, we may further obtain some rate of convergence results. This work does not focus on rate of convergence analysis, and results we obtain are not necessarily tight. Before stating a more general and more complicated result, we first present a version for constant stepsize logistic boosting, which is much easier to understand.

Theorem 3.2 *Consider the logistic regression loss function, with basis S which satisfies $R_m(S) \leq \frac{C_S}{\sqrt{m}}$ for some positive constant C_S. For each sample size m, consider Algorithm 2.1 with $f_0 = 0$,*

$\sup_k \Lambda_k = h_0(m) \leq 1/\sqrt{m}$, *and* $\epsilon_k \leq h_0(m)^2/2$. *Assume that we run boosting for* $k(m) = \beta_m/h_0(m)$ *steps, then*

$$E_{Z_1^m} Q(\hat{f}_{\hat{k}}) \leq \inf_{\bar{f} \in \mathrm{span}(S)} \left[Q(\bar{f}) + \frac{(2C_S+1)\beta_m}{\sqrt{m}} + \frac{\|\bar{f}\|_1 + 1}{\sqrt{m}} + \frac{\|\bar{f}\|_1}{\|\bar{f}\|_1 + \beta_m} \right].$$

Note that the condition $R_m(S) \leq C_S/\sqrt{m}$ is satisfied for many basis function classes such as two-level neural networks and tree basis functions (see Section 4.3). The bound in Theorem 3.2 is independent of $h_0(m)$ (as long as $h_0(m) \leq m^{-1/2}$). Although this bound is likely to be sub-optimal for practice problems, it does give a worst case guarantee for boosting with the greedy optimization aspect taken into consideration. Assume that there exists $\bar{f} \in \mathrm{span}(S)$ such that $Q(\bar{f}) = \inf_{f \in \mathrm{span}} Q(f)$. Then we may choose β_m as $\beta_m = O(\|\bar{f}\|_1^{1/2} m^{1/4})$, which gives a convergence rate of $E_{Z_1^m} Q(\hat{f}_{\hat{k}}) \leq Q(\bar{f}) + O(\|\bar{f}\|_1^{1/2} m^{-1/4})$. As the target complexity $\|\bar{f}\|_1$ increases, the convergence becomes slower. An example is provided in Section 6 to illustrate this phenomenon.

We now state the more general result, which Theorem 3.2 is based on (See Section 5.3).

Theorem 3.3 *Under Assumption 3.2, and let* $\phi(f) \geq 0$ *be a loss function such that* $A(f)$ *satisfies Assumption 3.1 with the choice* $\psi(a) = a$. *Give a sample size* m, *we pick a positive non-increasing sequence* $\{h_k\}$ *which may depend on* m. *Consider Algorithm 2.1 with* $f_0 = 0$, $\sup_k \Lambda_k = h_k$, *and* $\epsilon_k \leq h_k^2 M(s_{k+1})/2$, *where* $s_k = \sum_{i=0}^{k-1} h_i$.

Given training data, suppose we run boosting for $\hat{k} = k(m)$ *steps, and let* $\beta_m = s_{k(m)}$. *Then* $\forall \bar{f} \in \mathrm{span}(S)$ *such that* $Q(\bar{f}) \leq Q(0)$*:*

$$E_{Z_1^m} Q(\hat{f}_{\hat{k}}) \leq Q(\bar{f}) + 2\gamma_\phi(\beta_m)\beta_m R_m(S) + \frac{1}{\sqrt{m}}\phi(-\|\bar{f}\|_1) + \frac{\|\bar{f}\|_1 \phi(0)}{\|\bar{f}\|_1 + \beta_m} + \delta_m(\|\bar{f}\|_1),$$

where

$$\delta_m(\|\bar{f}\|_1) = \inf_{1 \leq \ell \leq k(m)} \left[\frac{s_\ell + \|\bar{f}\|_1}{\beta_m + \|\bar{f}\|_1} h_0^2 \ell + (k(m) - \ell) h_\ell^2 \right] M(\beta_m + h_{k(m)}).$$

If the target function is $\bar{f}$ which belongs to $\mathrm{span}(S)$, then Theorem 3.3 can be directly interpreted as a rate of convergence result. However, the expression of δ_m may still be quite complicated. For specific loss function and stepsize choices, the bound can be simplified. For example, the result for logistic boosting in Theorem 3.2 follows easily from the theorem (see Section 5.3).

4 Preparatory Results

As discussed ealier, it is well-known by now that boosting can overfit if left to run until convergence. In the previous Section 3.3 we stated our main results that with appropriately chosen stopping rules and under regularity conditions, results of consistency and rates of convergence can be obtained. In this section, we begin the proof process of these main results by proving the necessary preparatory

results, which are interesting in their own rights, especially those on numerical convergence of boosting in Section 4.1.

Suppose that we run Algorithm 2.1 on sample Z_1^m and stop at step $\hat{k}$. By triangle inequality and for any $\bar{f} \in \text{span}(S)$, we have

$$\begin{aligned} & E_{Z_1^m} Q(\hat{f}_{\hat{k}}) - Q(\bar{f}) \\ \leq & E_{Z_1^m} |\hat{Q}(\hat{f}_{\hat{k}}) - Q(\hat{f}_{\hat{k}})| + E_{Z_1^m} |\hat{Q}(\bar{f}) - Q(\bar{f})| + E_{Z_1^m} [\hat{Q}(\hat{f}_{\hat{k}}) - \hat{Q}(\bar{f})]. \end{aligned} \tag{9}$$

The middle-term is on a fixed $\bar{f}$, and thus it has a rate of convergence $O(1/\sqrt{m})$ by CLT. To study the consistency and rates of convergence of boosting with early stopping, the work lies in dealing with the first and third terms in (9). The third term is on the empirical performance of the boosting algorithm, and thus a numerical convergence analysis is required and hence proved in Section 4.1. Using modern empirical process theory, we can upper bound in Section 4.2 the first term in terms of Rademacher complexity.

We will focus on the loss functions (such that those in Appendix A) which satisfy Assumption 3.1. In particular we assume that ψ is a monotonic increasing function so that minimizing $A(f)$ or $\hat{A}(f)$ is equivalent to minimizing $Q(f)$ or $\hat{Q}(f)$. The derivation in Section 4.2 works with $Q(f)$ and $\hat{Q}(f)$ directly, instead of $A(f)$ and $\hat{A}(f)$. The reason is that, unlike our convergence analysis in Section 4.1, the relatively simple sample complexity analysis presented in Section 4.2 does not take advantage of ψ.

4.1 Numerical Convergence Analysis

Here we consider the numerical convergence behavior of f_k obtained from the greedy boosting procedure as k increases. For notational simplicity, we state the convergence results in terms of the population boosting algorithm, even though they also hold for the empirical boosting algorithm. The proofs of the two main lemmas are deferred to Appendix B.

In our convergence analysis, we will specify convergence bounds in terms of $\|\bar{f}\|_1$ (where $\bar{f}$ is a reference function) and a sequence of non-decreasing numbers s_k satisfying the following condition: there exist positive numbers h_k's such that

$$|\bar{\alpha}_k| \leq h_k \in \Lambda_k, \text{ and let } s_k = \|f_0\|_1 + \sum_{i=0}^{k-1} h_i, \tag{10}$$

where $\{\bar{\alpha}_k\}$ are the step-sizes in (3). Note that h_k in (10) can be taken as any number that satisfies the above condition, and it can depend on$\{\bar{\alpha}_k\}$ computed by the boosting algorithm. However, it is often desirable to state a convergence result that does not depend on the actually boosting outputs (that is the actual $\bar{\alpha}_k$ computed). For such results, we may simply fix h_k by letting $h_k = \sup \Lambda_k$. This gives convergence bounds for the restricted step size method which we mentioned earlier.

It can be shown (see Appendix B) that even in the worse case, the value $A(f_{k+1}) - A(\bar{f})$ decreases from $A(f_k) - A(\bar{f})$ by a reasonable quantity. Cascading this analysis leads to a numerical rate or speed of convergence for the boosting procedure.

The following lemma contains the one-step convergence bound, which is the key result in our convergence analysis.

Lemma 4.1 *Assume that $A(f)$ satisfies Assumption 3.1. Consider h_k and s_k that satisfy (10). Let $\bar{f}$ be an arbitrary reference function in* $\mathrm{span}(S)$*, and define*

$$\Delta A(f_k) = \max(0, A(f_k) - A(\bar{f})) \tag{11}$$

$$\bar{\epsilon}_k = \frac{h_k^2}{2} M(s_{k+1}) + \epsilon_k. \tag{12}$$

Then after k-steps, the following bound holds for f_{k+1} obtained from Algorithm 2.1:

$$\Delta A(f_{k+1}) \leq \left(1 - \frac{h_k}{s_k + \|\bar{f}\|_1}\right) \Delta A(f_k) + \bar{\epsilon}_k. \tag{13}$$

Applying Lemma 4.1 repeatedly, we arrive at a convergence bound for the boosting algorithm (2.1) as in the following lemma.

Lemma 4.2 *Under the assumptions of Lemma 4.1, we have*

$$\Delta A(f_k) \leq \frac{\|f_0\|_1 + \|\bar{f}\|_1}{s_k + \|\bar{f}\|_1} \Delta A(f_0) + \sum_{j=1}^{k} \frac{s_j + \|\bar{f}\|_1}{s_k + \|\bar{f}\|_1} \bar{\epsilon}_{j-1}. \tag{14}$$

The above lemma gives a quantitative bound on the convergence of $A(f_k)$ to the value $A(\bar{f})$ of an arbitrary reference function $\bar{f} \in \mathrm{span}(S)$. We can see that the numerical convergence speed of $A(f_k)$ to $A(\bar{f})$ depends on $\|\bar{f}\|_1$ and the accumulated or total step size s_k. Specifically, if we choose $\bar{f}$ such that $A(\bar{f}) \leq A(f_0)$, then it follows from the above bound that

$$A(f_{k+1}) \;\leq\; A(\bar{f}) \left\{1 - \frac{s_0 + \|\bar{f}\|_1}{s_{k+1} + \|\bar{f}\|_1}\right\} + \frac{s_0 + \|\bar{f}\|_1}{s_{k+1} + \|\bar{f}\|_1} A(f_0) + \sum_{j=0}^{k} \frac{s_{j+1} + \|\bar{f}\|_1}{s_{k+1} + \|\bar{f}\|_1} \bar{\epsilon}_j. \tag{15}$$

Note that the inequality is automatically satisfied when $A(f_{k+1}) \leq A(\bar{f})$.

Clearly in order to select $\bar{f}$ to optimize the bound on the right hand side, we need to balance a trade-off: we may select $\bar{f}$ such that $A(\bar{f})$ (and thus the first term) becomes smaller as we increase $\|\bar{f}\|_1$; however the other two terms will become large when $\|\bar{f}\|_1$ increases. This bound also reveals the dependence of the convergence on the initial value of the algorithm f_0: the closer of $A(f_0)$ to the infinimum of A, the smaller the bound. To our knowledge, this is the first convergence bound for greedy boosting procedures with quantitative numerical convergence speed information.

Previous analyses, including matching pursuit for least squares [29], Breiman's analysis [9] of the exponential loss, as well as the Bregman divergence bound in [12] and the analysis of gradient boosting in [31], were all limiting results without any information on the numerical speed of convergence. The key conceptual difference here is that we do not compare to the optimal value

directly, but instead, to the value of an arbitrary $\bar{f} \in \mathrm{span}(S)$ so that $\|\bar{f}\|_1$ can be used to measure the convergence speed. This approach is also crucial for problems where $A(\cdot)$ can take $-\infty$ as its infinimum for which a direct comparison will clearly fail (for example, Breiman's exponential loss analysis requires smoothness assumptions to prevent this $-\infty$ infinimum value).

A general limiting convergence result follows directly from the above lemma.

Theorem 4.1 *Assume that $\sum_{j=0}^{\infty} \bar{\epsilon}_j < \infty$ and $\sum_{j=0}^{\infty} h_j = \infty$, then we have the following optimization convergence result for the greedy boosting algorithm (2.1):*

$$\lim_{k\to\infty} A(f_k) = \inf_{f\in \mathrm{span}(S)} A(f).$$

Proof. The assumptions imply that $\lim_{k\to\infty} s_k = \infty$. We can thus construct a non-negative integer valued function $k \to j(k) \leq k$ such that $\lim_{k\to\infty} s_{j(k)}/s_k = 0$ and $\lim_{k\to\infty} s_{j(k)} = \infty$.

From Lemma 4.2, we obtain for any fixed $\bar{f}$:

$$\begin{aligned}
\Delta A(f_k) \leq & \frac{\|f_0\|_1 + \|\bar{f}\|_1}{s_k + \|\bar{f}\|_1} \Delta A(f_0) + \sum_{j=1}^{k} \frac{s_j + \|\bar{f}\|_1}{s_k + \|\bar{f}\|_1} \bar{\epsilon}_{j-1} \\
= & o(1) + \sum_{j=1}^{j(k)} \frac{s_j + \|\bar{f}\|_1}{s_k + \|\bar{f}\|_1} \bar{\epsilon}_{j-1} + \sum_{j=j(k)+1}^{k} \frac{s_j + \|\bar{f}\|_1}{s_k + \|\bar{f}\|_1} \bar{\epsilon}_{j-1} \\
\leq & o(1) + \frac{s_{j(k)} + \|\bar{f}\|_1}{s_k + \|\bar{f}\|_1} \sum_{j=1}^{j(k)} \bar{\epsilon}_{j-1} + \sum_{j=j(k)+1}^{k} \bar{\epsilon}_{j-1} = o(1).
\end{aligned}$$

Therefore $\lim_{k\to\infty} \max(0, A(f_k) - A(\bar{f})) = 0$. Since our analysis applies to any $\bar{f} \in \mathrm{span}(S)$, we can choose $\bar{f}_j \in \mathrm{span}(S)$ such that $\lim_j A(\bar{f}_j) = \inf_{f\in\mathrm{span}(S)} A(f)$. Now from $\lim_{k\to\infty} \max(0, A(f_k) - A(\bar{f}_j)) = 0$, we obtain the theorem. □

Corollary 4.1 *For loss functions such as those in Appendix A, we have $\sup_a M(a) < \infty$. Therefore as long as there exist h_j in (10) and ϵ_j in (3) such that $\sum_{j=0}^{\infty} h_j = \infty$, $\sum_{j=0}^{\infty} h_j^2 < \infty$, and $\sum_{j=0}^{\infty} \epsilon_j < \infty$, we have the following convergence result for the greedy boosting procedure:*

$$\lim_{k\to\infty} A(f_k) = \inf_{f\in \mathrm{span}(S)} A(f).$$

The above results regarding population minimization automatically apply to the empirical minimization if we assume that the starting point f_0, as well as quantities ϵ_k and Λ_k in (3), are sample-independent, and the restricted step-size case where $h_k = \sup \Lambda_k$ satisfies the condition (4).

The idea of restricting the step size when we compute $\bar{\alpha}_j$ was advocated by Friedman, who discovered empirically that taking small step size helps [14]. In our analysis, we can restrict the search region so that Corollary 4.1 is automatically satisfied. Since we believe this is an important

case which applies for general loss functions, we shall explicitly state the corresponding convergence result below.

Corollary 4.2 *Consider a loss function (for example, those in Appendix A) such that* $\sup_a M(a) < +\infty$. *Pick any sequence of positive numbers* h_j $(j \geq 0)$ *such that* $\sum_{j=0}^{\infty} h_j = \infty$, $\sum_{j=0}^{\infty} h_j^2 < \infty$. *If we choose* Λ_k *in Algorithm 2.1 such that* $h_k = \sup \Lambda_k$, *and* ϵ_j *in (3) such that* $\sum_{j=0}^{\infty} \epsilon_j < \infty$, *then*

$$\lim_{k\to\infty} A(f_k) = \inf_{f\in \mathrm{span}(S)} A(f).$$

Note that the above result requires that the step size h_j to be small ($\sum_{j=0}^{\infty} h_j^2 < \infty$), but also not too small ($\sum_{j=0}^{\infty} h_j = \infty$). As discussed above, the first condition prevents large oscillation. The second condition is needed to ensure that f_k can cover the whole space $\mathrm{span}(S)$.

The above convergence results are limiting results that do not carry any convergence speed information. Although with specific choices of h_k and s_k, one may obtain such information from (14), the second term on the right hand side is typically quite complicated. It is thus useful to state a simple result for a specific choice of h_k and s_k, which yields more explicit convergence information.

Corollary 4.3 *Assume that* $A(f)$ *satisfies Assumption 3.1. Pick a sequence of non-increasing positive numbers* h_j $(j \geq 0)$. *Suppose we choose* Λ_k *in Algorithm 2.1 such that* $h_k = \sup \Lambda_k$, *and choose* ϵ_k *in (3) such that* $\epsilon_k \leq h_k^2 M(s_{k+1})/2$. *If we start Algorithm 2.1 with* $f_0 = 0$, *then*

$$\Delta A(f_k) \leq \frac{\|\bar{f}\|_1}{s_k + \|\bar{f}\|_1} \Delta A(f_0) + \inf_{1\leq \ell \leq k} \left[\frac{\ell(s_\ell + \|\bar{f}\|_1)}{s_k + \|\bar{f}\|_1} h_0^2 + (k-\ell) h_\ell^2 \right] M(s_{k+1}).$$

Proof. Using notations of Lemma 4.1, we have $\bar{\epsilon}_k \leq h_\ell^2 M(s_{k+1})$. Therefore each summand in the second term on the right hand size of Lemma 4.2 is no more than $h_\ell^2 M(s_{k+1})$ when $j > \ell$ and is no more than $h_0^2 M(s_{k+1})(s_\ell + \|\bar{f}\|_1)/(s_k + \|\bar{f}\|_1)$ when $j \leq \ell$. The desired inequality is now a straight-forward consequence of (14). □

Note that similar to the proof of Theorem 4.1, the term $(k-\ell)h_\ell^2$ in Corollary 4.3 can also be replaced by $\sum_{j=\ell+1}^{k} h_j^2$. A special case of Corollary 4.3 is the constant step-size ($h_k = h_0$) boosting, which is the original version of restricted step size boosting considered by Friedman [14]. This method is simple to apply since there is only one step-size parameter to choose. Corollary 4.3 shows that boosting with constant step-size (also referred to as ϵ-boosting in the literature) converges to the optimal value in the limit of $h_0 \to 0$, as long as we choose the number of iterations k and step size h_0 such that $kh_0 \to \infty$ and $kh_0^2 \to 0$. To the best of our knowledge, this is the only rigorously stated convergence result for the ϵ-boosting method, which justifies why one needs to use a step-size that is as small as possible.

It is also possible to handle sample-dependent choices of Λ_k in Algorithm 2.1, or allow unrestricted step size ($\Lambda_k = R$) for certain formulations. However, the corresponding analysis becomes much more complicated. According to Friedman [14], the restricted step-size boosting procedure is preferable in practice. Therefore we shall not provide a consistency analysis for unrestricted

step-size formulations in this paper; but see Appendix C for relaxations of the restricted step-size condition.

In addition to the above convergence results for general boosting algorithms, Lemma 4.2 has another very useful consequence regarding the limiting behavior of Adaboost in the separable classification case. It asserts that the infinitely small step-size version of AdaBoost, in the convergence limit, is an L_1 margin maximizer. This result has been observed through a connection between Boosting with early stopping and L_1 constrained boosting (see [17]). Our analysis gives a direct and rigorous proof. This result is interesting because it shows that AdaBoost shares some similarity (in the limit) with Support Vector Machines (SVMs) whose goal in the separable case is to find maximum margin classifiers and the concept of margin has been popularized by Vapnik [36] who used it to analyze the generalization performance of SVMs. The detailed analysis is provided in Appendix D.

4.2 Uniform Convergence

There are a number of possible ways to study the uniform convergence of empirical processes. In this section, we use a relatively simple approach based on Rademacher complexity. Examples with neural networks and tree-basis (left orthants) functions will be given to illustrate our analysis.

The Rademacher complexity approach for analyzing boosting algorithms appeared first in [21]. Due to its simplicity and elegancy, it has been used and generalized by many researchers [3, 2, 4, 6, 30]. The approach used here essentially follows Theorem 1 of [21] but without concentration results.

From Lemma 4.2, we can see that the convergence of the boosting procedure is closely related to $\|\bar{f}\|_1$ and $\|f_k\|_1$. Therefore it is natural for us to measure the learning complexity of Algorithm 2.1 based on 1-norm of the function family it can approximate at any given step. We shall mention that this analysis is not necessarily the best approach for obtaining tight learning bounds since the boosting procedure may effectively search a much smaller space than the function family measured by the one-norm $\|f_k\|_1$. However it is relatively simple, and sufficient for our purpose of providing an early-stopping strategy to give consistency and some rates of convergence results.

Given any $\beta > 0$, we now would like to estimate the rate of uniform convergence:

$$R_m^\beta = E_{Z_1^m} \sup_{\|f\|_1 \le \beta} (Q(f) - \hat{Q}(f)),$$

where Q and $\hat{Q}$ are defined in (8).

The concept of Rademacher complexity used in our analysis is given in Definition 3.2. For simplicity, our analysis also employs Assumption 3.2. As mentioned earlier, the conditions are not essential, but rather they simplifies the final results. For example, the condition (7) implies that $\forall f \in \text{span}(S)$, $|f(x)| \le \|f\|_1$. It follows that $\forall \beta \ge \|f\|_1$, $\phi(f, y) \le \phi(-\beta)$. This inequality, although convenient, is certainly not essential.

Lemma 4.3 *Under Assumption 3.2,*

$$R_m^\beta = E_{Z_1^m} \sup_{\|f\|_1 \le \beta} [E_D \phi(f(X), Y) - \hat{E}\phi(f(X), Y)] \le 2\gamma_\phi(\beta)\beta R_m(S), \tag{16}$$

where $\gamma_\phi(\beta)$ be a Lipschitz constant of ϕ in $[-\beta, \beta]$: $\forall |f_1|, |f_2| \le \beta : |\phi(f_1) - \phi(f_2)| \le \gamma_\phi(\beta)|f_1 - f_2|$.

Proof: Using the standard symmetrization argument (for example, see Lemma 2.3.1 of [35]), we have

$$R_m^\beta = E_{Z_1^m} \sup_{\|f\|_1 \le \beta} [E_D \phi(f(X), Y) - \hat{E}\phi(f(X), Y)] \le 2R_m(\{\phi(f(X), Y) : \|f\|_1 \le \beta\}).$$

Now the one-sided Rademacher process comparison result in [32] (Theorem 7), which is essentially a slightly refined result (with better constant) of the two sided version in [24] (Theorem 4.12), implies that

$$R_m(\{\phi(f(X), Y) : \|f\|_1 \le \beta\}) \le \gamma_\phi(\beta) R_m(\{f(X) : \|f\|_1 \le \beta\}).$$

Using the simple fact that $g = \sum_i \alpha_i f_i$ ($\sum_i |\alpha_i| = 1$) implies $g \le \max(\sup_i f_i, \sup_i -f_i)$, and that S is closed under negation, it is easy to verify that $R_m(S) = R_m(\{f \in \mathrm{span}(S) : ||f||_1 \le 1\})$. Therefore

$$R_m(\{f(X) : \|f\|_1 \le \beta\}) = \beta R_m(S).$$

Now by combining the three inequalities, we obtain the lemma. □

4.3 Estimating Rademacher Complexity

Our uniform convergence result depends on the Rademacher complexity $R_m(S)$. For many function classes, it can be estimated directly. In this section, we use a relation between Rademacher complexity and ℓ_2-covering numbers from [35].

Let $X = \{X_1, \ldots, X_m\}$ be a set of points and let Q_m be the uniform probability measure over these points. We define the $\ell_2(Q_m)$ distance between any two functions f and g as

$$\ell_2(Q_m)(f, g) = \left(\frac{1}{m} \sum_{i=1}^m |f(x_i) - g(x_i)|^2 \right)^{1/2}.$$

Let F be a class of functions, the *empirical ℓ_2-covering number* of F, denoted by $N(\epsilon, F, \ell_2(Q_m))$, is the minimal number of balls $\{g : \ell_2(Q_m)(g, f) \le \epsilon\}$ of radius ϵ needed to cover F. The *uniform ℓ_2 covering number* is given by

$$N_2(\epsilon, F, m) = \sup_{Q_m} N(\epsilon, F, \ell_2(Q_m)),$$

where the supremum is over all probability distribution Q_m over samples of size m. If F contains

0, then there exists a universal constant C (see Corollary 2.2.8 in [35]):

$$R_m(F) \leq \left(\int_0^\infty \sqrt{\log N_2(\epsilon, F, m)} d\epsilon \right) \frac{C}{\sqrt{m}},$$

where we assume that the integral on the right hand side is finite. Note that for a function class F with divergent integration value on the right hand side, the above inequality can be easily modified so that we start the integration from a point $\epsilon_0 > 0$ instead of 0. However, the dependency of $R_m(F)$ on m can be slower than $1/\sqrt{m}$.

Assumption 4.1 *F satisfies the following condition:*

$$\sup_m \int_0^\infty \sqrt{\log N_2(\epsilon, F, m)} d\epsilon < \infty.$$

A function class F that satisfies Assumption 4.1 is also a Donsker class, for which the central limit theorem holds. In statistics and machine learning, one often encounters function classes F with finite VC-dimension, where the following condition holds (see Theorem 2.6.7 of [35]) for some constants C and V independent of m: $N_2(\epsilon, F, m) \leq C\,(1/\epsilon)^V$. Clearly a function class with finite VC-dimension satisfies Assumption 4.1.

For simplicity, in this paper, we assume that S satisfies Assumption 4.1. It follows that

$$R_m(S) \leq R_m(S \cup \{0\}) \leq \frac{C_S}{\sqrt{m}}, \tag{17}$$

where C_S is a constant that depends on S only. This is the condition used in Theorem 3.2. We give two examples of basis functions that are often used in practice with boosting.

Two-level neural networks

We consider two level neural-networks in R^d, which form the function space span(S) with S given by

$$S = \{\sigma(w^T x + b) : w \in R^d, b \in R\},$$

where $\sigma(\cdot)$ is a monotone bounded continuous activation function.

It is well-known that S has a finite VC-dimension, and thus satisfies Assumption 4.1. In addition, for any compact subset $U \in R^d$, it is also well known that span(S) is dense in $C(U)$ (see [26]).

Tree-basis functions

Tree-basis (left orthants) functions in R^d are given by the indicator function of rectangular regions:

$$S = \{I((-\infty, a_1] \times \cdots \times (-\infty, a_d]) : a_1, \ldots, a_d \in R\}.$$

Similar to two-level neural networks, it is well known that S has a finite VC-dimension, and for any compact set $U \in R^d$, span(S) is dense in $C(U)$.

In addition to rectangular region basis functions, we may also consider basis S consisted of restricted size classification and regression trees (disjoint unions of constant functions on rectangular regions), where we assume that the number of terminal nodes is no more than a constant V. Such a basis set S also has a finite VC-dimension.

5 Consistency and rates of convergence with early stopping

In this section, we put together the results in the preparatory Section 4 to prove the consistency and some rates of convergence results for Algorithm 2.1 as stated in the main result Section 3.3. For simplicity we consider only restricted step-size boosting with relatively simple strategies for choosing step-sizes. According to Friedman [14], the restricted step-size boosting procedure is preferable in practice. Therefore we shall not provide a consistency analysis for unrestricted step-size formulations in this paper. Discussions on the relaxation of the stepsize condition can be found in Appendix C.

5.1 General Decomposition

Suppose that we run the boosting algorithm and stop at an early stopping point $\hat{k}$. The quantity $\hat{k}$, which is to be specified later in Section 5.2, may depend on the empirical sample Z_1^m. Suppose also that the stopping point $\hat{k}$ is chosen so that the resulting boosting estimator $\hat{f}_{\hat{k}}$ satisfies

$$\lim_{m\to\infty} E_{Z_1^m} Q(\hat{f}_{\hat{k}}) = \inf_{f\in \mathrm{span}(S)} Q(f), \tag{18}$$

where we use $E_{Z_1^m}$ to denote the expectation with respect to the random sample Z_1^m. Since $Q(\hat{f}_{\hat{k}}) \geq \inf_{f\in\mathrm{span}(S)} Q(f)$, we also have

$$\lim_{m\to\infty} E_{Z_1^m} |Q(\hat{f}_{\hat{k}}) - \inf_{f\in\mathrm{span}(S)} Q(f)| = \lim_{m\to\infty} E_{Z_1^m} Q(\hat{f}_{\hat{k}}) - \inf_{f\in\mathrm{span}(S)} Q(f) = 0.$$

If we further assume there is an unique f^* such that

$$Q(f^*) = \inf_{f\in\mathrm{span}(S)} Q(f)$$

and for any sequence $\{f_m\}$: $Q(f_m) \to Q(f^*)$ implies that $f_m \to f^*$. Then since $Q(\hat{f}_{\hat{k}}) \to Q(f^*)$ as $m \to \infty$, it follows that

$$\hat{f}_{\hat{k}} \to f^* \quad \text{in probability,}$$

which gives the usual consistency of the boosting estimator with an appropriate early stopping if the target function f coincides with f^*. This is the case for example if the regression function $f(x) = E_D(Y|x)$ with respect to the true distribution D is in span(S) or can be approximated arbitrarily close by functions in span(S).

In the following, we derive a general decomposition needed for proving (18) or Theorem 3.1 in

Section 3.3. Suppose that Assumption 3.2 holds, then for all fixed $\bar{f} \in \mathrm{span}(S)$, we have

$$\begin{aligned} E_{Z_1^m} |\hat{Q}(\bar{f}) - Q(\bar{f})| &\leq \left[E_{Z_1^m} |\hat{Q}(\bar{f}) - Q(\bar{f})|^2 \right]^{1/2} \\ &= \left[\frac{1}{m} E_D |\phi(\bar{f}(X)Y) - Q(\bar{f})|^2 \right]^{1/2} \\ &\leq \left[\frac{1}{m} E_D \phi(\bar{f}(X)Y)^2 \right]^{1/2} \leq \frac{1}{\sqrt{m}} \phi(-\|\bar{f}\|_1). \end{aligned}$$

Assume that we run Algorithm 2.1 on sample Z_1^m and stop at step $\hat{k}$. If the stopping point $\hat{k}$ satisfies $P(\|\hat{f}_{\hat{k}}\|_1 \leq \beta_m) = 1$ for some sample-independent $\beta_m \geq 0$, then using the uniform convergence estimate in (16), we obtain

$$\begin{aligned} & E_{Z_1^m} Q(\hat{f}_{\hat{k}}) - Q(\bar{f}) \\ =& E_{Z_1^m} [Q(\hat{f}_{\hat{k}}) - \hat{Q}(\hat{f}_{\hat{k}})] + E_{Z_1^m} [\hat{Q}(\bar{f}) - Q(\bar{f})] + E_{Z_1^m} [\hat{Q}(\hat{f}_{\hat{k}}) - \hat{Q}(\bar{f})] \\ \leq& 2\gamma_\phi(\beta_m)\beta_m R_m(S) + \frac{1}{\sqrt{m}} \phi(-\|\bar{f}\|_1) + \sup_{Z_1^m} [\hat{Q}(\hat{f}_{\hat{k}}) - \hat{Q}(\bar{f})]. \end{aligned} \tag{19}$$

5.2 Consistency with Restricted Step-size Boosting

We consider a relatively simple early-stopping strategy for restricted step-size boosting, where we take $h_k = \sup \Lambda_k$ to satisfy (4).

Clearly, in order to prove consistency, we only need to stop at a point such that $\forall \bar{f} \in \mathrm{span}(S)$, all three terms in (19) become non-positive in the limit $m \to \infty$. By estimating the third term using Lemma 4.2, we obtain the following proof of our main consistency result (Theorem 3.1).

Proof of Theorem 3.1. Obviously the assumptions of the theorem imply that the first two terms of (19) automatically converge to zero. In the following, we only need to show that $\forall \bar{f} \in \mathrm{span}(S)$: $\sup_{Z_1^m} \max(0, \hat{Q}(\hat{f}_{\hat{k}}) - \hat{Q}(\bar{f})) \to 0$ when $m \to \infty$.

From Appendix A, we know that there exists a distribution independent number $M > 0$ such that $M(a) < M$ for all underlying distributions. Therefore for all empirical sample Z_1^m, Lemma 4.2 implies that

$$\Delta\hat{A}(\hat{f}_{\hat{k}}) \leq \frac{\|f_0\|_1 + \|\bar{f}\|_1}{s_{\hat{k}} + \|\bar{f}\|_1} \Delta\hat{A}(f_0) + \sum_{j=1}^{\hat{k}} \frac{s_j + \|\bar{f}\|_1}{s_{\hat{k}} + \|\bar{f}\|_1} \bar{\epsilon}_{j-1},$$

where $\Delta\hat{A}(f) = \max(0, \hat{A}(f) - \hat{A}(\bar{f}))$, $s_k = \|f_0\|_1 + \sum_{i=0}^{k-1} h_i$, and $\bar{\epsilon}_k = \frac{h_k^2}{2} M + \epsilon_k$. Now using the inequality $\Delta\hat{A}(f_0) \leq \max(\psi(\phi(-\|f_0\|_1)) - \psi(\phi(\|\bar{f}\|_1)), 0) = c(\bar{f})$, and $\hat{k} \geq k_m$, we obtain

$$\sup_{Z_1^m} \Delta\hat{A}(\hat{f}_{\hat{k}}) \leq \sup_{k \geq k_m} \left[\frac{\|f_0\|_1 + \|\bar{f}\|_1}{s_k + \|\bar{f}\|_1} c(\bar{f}) + \sum_{j=1}^{k} \frac{s_j + \|\bar{f}\|_1}{s_k + \|\bar{f}\|_1} \bar{\epsilon}_{j-1} \right]. \tag{20}$$

Observe that the right hand side is independent of the sample Z_1^m. From the assumptions of the theorem, we have $\sum_{j=0}^{\infty} \bar{\epsilon}_j < \infty$ and $\lim_{k \to \infty} s_k = \infty$. Now the proof of Theorem 4.1 implies that

as $k_m \to \infty$, the right hand side of (20) converges to zero. Therefore $\lim_{m\to\infty} \sup_{Z_1^m} \Delta\hat{A}(\hat{f}_{\hat{k}}) = 0$. □

The following universal consistency result is a straight-forward consequence of Theorem 3.1:

Corollary 5.1 *Under the assumptions of Theorem 3.1. For any Borel set $U \subset R^d$, if* span(S) *is dense in $C(U)$ — the set of continuous functions under the uniform-norm topology, then for all Borel measure D on $U \times \{-1, 1\}$,*

$$\lim_{m\to\infty} E_{Z_1^m} Q(\hat{f}_{\hat{k}}) = \inf_{f\in B(U)} Q(f),$$

where $B(U)$ is the set of Borel measurable functions.

Proof. We only need to show $\inf_{f\in\text{span}(S)} Q(f) = \inf_{f\in B(U)} Q(f)$. This follows directly from Theorem 4.1 of [38]. □

For binary classification problems where $y = \pm 1$, given any real-valued function f, we predict $y = 1$ if $f(x) \geq 0$ and $y = -1$ if $f(x) < 0$. The classification error is the following $0-1$ loss function:

$$\ell(f(x), y) = I[yf(x) \leq 0],$$

where $I[E]$ is the indicator function of the event E, and the expected loss is

$$L(f) = E_D \ell(f(X), Y). \tag{21}$$

The goal of classification is to find a predictor f to minimize (21). Using the notation $\eta(x) = P(Y = 1|X = x)$, it is well known that L^*, the minimum of $L(f)$, can be achieved by setting $f(x) = 2\eta(x) - 1$. Let D be a Borel measure defined on $U \times \{-1, 1\}$, it is known (for example, see [38]) that if $Q(f) \to \inf_{f\in B(U)} Q(f)$, then $L(f) \to L^*$. We thus have the following consistency result for binary-classification problems:

Corollary 5.2 *Under the assumptions of Corollary 5.1, we have*

$$\lim_{m\to\infty} E_{Z_1^m} L(\hat{f}_{\hat{k}}) = L^*.$$

The stopping criterion given in Theorem 3.1 depends on $R_m(S)$. For S that satisfies Assumption 4.1, this can be estimated from (17). The condition $\gamma_\phi(\beta_m)\beta_m R_m(S) \to 0$ in Theorem 3.1 becomes $\gamma_\phi(\beta_m)\beta_m = o(\sqrt{m})$. Using the bounds for $\gamma_\phi(\cdot)$ in Section 4.2, we obtain the following condition:

Assumption 5.1 *Sequence β_m satisfies:*

- *Logistic regression $\phi(f) = \ln(1 + \exp(-f))$: $\beta_m = o(m^{1/2})$.*
- *Exponential $\phi(f) = \exp(-f)$: $\beta_m = o(\log m)$.*
- *Least squares $\phi(f) = (f-1)^2$: $\beta_m = o(m^{1/4})$.*

- *Modified least squares* $\phi(f) = \max(0, 1-f)^2$*:* $\beta_m = o(m^{1/4})$.
- *p-norm* $\phi(f) = |f-1|^p$ *(*$p \geq 2$*):* $\beta_m = o(m^{1/2p})$.

We can summarize the above discussion in the following theorem, which applies to boosted VC-classes such as boosted trees and two-level neural networks.

Theorem 5.1 *Under Assumption 3.2, and let* ϕ *be one of the loss functions considered in Appendix A. Assume further that in Algorithm 2.1, we choose quantities* f_0*,* ϵ_k*, and* Λ_k *to be independent of the sample* Z_1^m*, such that* $\sum_{j=0}^{\infty} \epsilon_j < \infty$*, and* $h_k = \sup \Lambda_k$ *satisfies (4).*

Suppose S *satisfies Assumption 4.1 and we choose sample-independent* $k_m \to \infty$*, such that* $\beta_m = \|f_0\|_1 + \sum_{j=0}^{k_m} h_j$ *satisfies Assumption 5.1. If we stop Algorithm 2.1 at step* k_m*, then* $\|\hat{f}_{k_m}\|_1 \leq \beta_m$ *and the following consistency result holds:*

$$\lim_{m\to\infty} E_{Z_1^m} Q(\hat{f}_{k_m}) = \inf_{f \in \mathrm{span}(S)} Q(f).$$

Mover, if $\mathrm{span}(S)$ *is dense in* $C(U)$ *for a Borel set* $U \subset R^d$*, then for all Borel measure* D *on* $U \times \{-1, 1\}$*, we have*

$$\lim_{m\to\infty} E_{Z_1^m} Q(\hat{f}_{k_m}) = \inf_{f \in B(U)} Q(f), \quad \lim_{m\to\infty} E_{Z_1^m} L(\hat{f}_{k_m}) = L^*.$$

Note that in the above theorem, the stopping criterion k_m is sample independent. However, similar to Theorem 3.1, we may allow other sample-dependent $\hat{k}$ such that $\|\hat{f}_{\hat{k}}\|_1$ stay within the β_m bound. One may be tempted to interpret the rates of β_m. However, since different loss functions approximate the underlying distribution in different ways, it is not clear that one can rigorously compare them. Moreover our analysis is likely to be loose.

5.3 Some Bounds on the Rate of Convergence

In addition to consistency, it is also useful to study statistical rates of convergence of greedy boosting method with certain target function classes. Since our analysis is based on 1-norm of the target function, the natural function class we may consider are those that can be approximated well using a function in $\mathrm{span}(S)$ with small 1-norm.

We would like to emphasize that rates results, that have been stated in Theorems 3.2 and 3.3 and to be proved here, are not necessarily optimal. There are several reasons for this. First, we relate the numerical behavior of boosting to 1-norm regularization. In reality, this may not always be the best way to analyze boosting since boosting can be studied using other complexity measures such as sparsity (for example, see [22] for some other complexity measures). Second, even with the 1-norm regularization complexity measure, the numerical convergence analysis in Section 4.1 may not be tight. This again will adversely affect our final bounds. Third, our uniform convergence analysis, based on the relatively simple Rademacher complexity, are not necessarily tight. For some problems, there are more sophisticated methods which improve upon our approach here (for example, see [3, 2, 5, 4, 6, 30, 22]).

A related point is that bounds we are interested in here are a priori convergence bounds that are data-independent. In recent years, there has been much interest in developing data-dependent bounds which are tighter (see references mentioned above). For example, in our case, we may allow β in (16) to depend on the observed data (rather than simply setting it to be a value based only on the sample-size). This approach, which can tighten the final bounds based on observation, is a quite significant recent theoretical advance. However, as mentioned above, there are other aspects of our analysis that can be loose. Moreover, we are mainly interested in worst case scenario upper bounds on the convergence behavior of boosting without looking at the data. Therefore we shall not develop data-dependent bounds here.

The statistical convergence behavior of the boosting algorithm relies on its numerical convergence behavior, which can be estimated using (14). Combined with statistical convergence analysis, we can easily obtain our main rate of convergence result in Theorem 3.3.

Proof of Theorem 3.3. From (19), we obtain

$$E_{Z_1^m} Q(\hat{f}_{\hat{k}}) \leq Q(\bar{f}) + 2\gamma_\phi(\beta_m)\beta_m R_m(S) + \frac{1}{\sqrt{m}}\phi(-\|\bar{f}\|_1) + \sup_{Z_1^m}[\hat{Q}(\hat{f}_{\hat{k}}) - \hat{Q}(\bar{f})].$$

Now we simply apply Corollary 4.3 to bound the last term. This leads to the desired bound. □

The result for logistic regression in Theorem 3.2 follows easily from Theorem 3.3.

Proof of Theorem 3.2. Consider logistic regression loss and constant step size boosting, where $h_k = h_0(m)$. Note that for logistic regression, we have $\gamma_\phi(\beta) \leq 1$, $M(a) \leq 1$, $\phi(-\|\bar{f}\|_1) \leq 1 + \|\bar{f}\|_1$, and $\phi(0) \leq 1$. Using these estimates, we obtain from Theorem 3.3:

$$E_{Z_1^m} Q(\hat{f}_{\hat{k}}) \leq Q(\bar{f}) + 2\beta_m R_m(S) + \frac{\|\bar{f}\|_1 + 1}{\sqrt{m}} + \frac{\|\bar{f}\|_1}{\|\bar{f}\|_1 + \beta_m} + \beta_m h_0(m).$$

Using the estimate of $R_m(S)$ in (17), and let $h_0(m) \leq 1/\sqrt{m}$, we obtain

$$E_{Z_1^m} Q(\hat{f}_{\hat{k}}) \leq Q(\bar{f}) + \frac{(2C_S + 1)\beta_m}{\sqrt{m}} + \frac{\|\bar{f}\|_1 + 1}{\sqrt{m}} + \frac{\|\bar{f}\|_1}{\|\bar{f}\|_1 + \beta_m}.$$

This leads to the claim. □

6 Experiments

The purpose of this section is not to reproduce the large number of already existing empirical studies on boosting. Although this paper is theoretical in nature, it is still useful to empirically examine various implications of our analysis, so that we can verify they have observable consequences. For this reason, our experiments focus mainly on aspects of boosting with early-stopping which have not been addressed in previous studies.

Specifically, we are interested in testing consistency and various issues of boosting with early-stopping based on our theoretical analysis. As pointed out in [28], experimentally testing consistency is a very challenging task. Therefore in this section, we have to rely on relatively simple

synthetic data, for which we can precisely control the problem and the associated Bayes risk. Such an experimental setup serves the purpose of illustrating main insights revealed by our theoretical analyses.

6.1 Experimental setup

In order to fully control the data generation mechanism, we shall use simple one-dimensional examples. A similar experimental setup was also used in [23] to study various theoretical aspects of voting classification methods.

Our goal is to predict $Y \in \{\pm 1\}$ based on $X \in [0,1]$. Throughout the experiments, X is uniformly distributed in $[0,1]$. We consider the target conditional probability of the form $P(Y = 1|X) = 2\{dX\}I(\{dX\} \leq 0.5) + 2(1-\{dX\})I(\{dX\} > 0.5)$, where $d \geq 1$ is an integer which controls the complexity of the target function, and I denotes the set indicator function. We have also used the notation $\{z\} = z - \lfloor z \rfloor$ to denote the decimal part of a real number z, with the standard notation of $\lfloor z \rfloor$ for the integer part of z. The Bayes error rate of our model is always 0.25.

Graphically, the target conditional probability contains d triangles. Figure 1 plots such a target for $d = 2$.

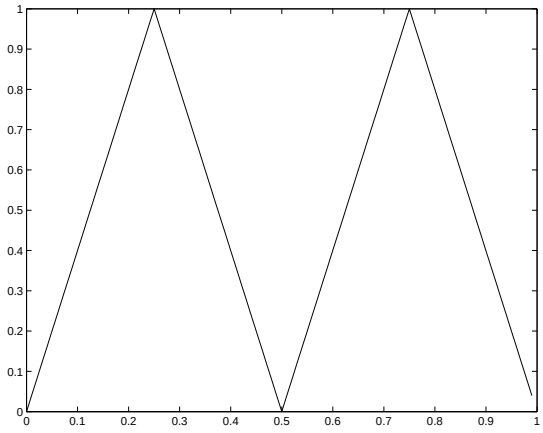

Figure 1: Target conditional probability for $d = 2$

We use one-dimensional stumps of the form $I([0,a])$ as our basis functions, where a is a parameter in $[0,1]$. They form a complete basis since each interval indicator function $I((a,b])$ can be expressed as $I([0,b]) - I([0,a])$.

There have been a number of experimental studies on the impact of using different convex loss functions (for example, see [28, 39, 27, 14]). Although our theoretical analysis applies to general loss functions, it is not refined enough to suggest that any one particular loss is better than another. For this reason, our experimental study will not include a comprehensive comparison of different loss functions. This task is better left to dedicated empirical studies (such as some of those mentioned above).

We will only focus on consequences of our analysis which has not been well-studied empirically.

These include various issues related to early-stopping and their impact on the performance of boosting. For this purpose, throughout the experiments, we shall only use the least-squares loss function. In fact, it is known that this loss function works quite well for many classification problems (see for example, [11, 27]), and has been widely applied to many pattern-recognition applications. Its simplicity also makes it attractive.

For the least squares loss, the target function which the boosting procedure tries to estimate is $f_*(x) = 2P(Y = 1|X = x) - 1$. In our experiments, unless otherwise noted, we use boosting with restricted stepsize, where at each iteration, we limit the step size to be no larger than $h_i = (i+1)^{-2/3}$. This choice satisfies our numerical convergence requirement, where we need the conditions $\sum_i h_i = \infty$ and $\sum_i h_i^2 < \infty$. Therefore it also satisfies the consistency requirement in Theorem 3.1.

6.2 Early stopping and over-fitting

Although it is known that boosting forever can overfit (for example, see [16, 19]), it is natural to begin our experiments by graphically showing the effect of early-stopping on the predicative performance of boosting.

We shall use the target conditional probability described earlier with complexity $d = 2$, and training sample size of 100. Figure 2 plots the graphs of estimators obtained after $k = 32, 1024$ boosting iterations. The dotted lines on the background show the true target function $f_*(x) = 2P(Y = 1|X = x)$. We can see that after 32 iterations, the boosting estimator, although not perfect, roughly has the same shape as that of the true target function. However, after 1024 iterations, the graph appears quite random, implying that the boosting estimator starts to overfit the data.

Figure 3 shows the predictive performance of boosting versus the number of iterations. The need for early-stopping is quite apparent in this example. The *excessive classification error* quantity is defined as the true classification error of the estimator minus the Bayes error (which is 0.25 in our case). Similarly, the *excessive convex loss* quantity is defined as the true least-squares loss of the estimator minus the optimal least squares loss of the target function $f_*(x)$. Both excessive classification error and convex loss are evaluated through numerical integration for a given decision rule. Moreover, as we can see from Figure 4, the training error continues to decrease as the number of boosting iterations increases, which eventually leads to overfitting of the training data.

6.3 Early stopping and total stepsize

Since our theoretical analysis favors restricted step size, a relevant question is what step size should we choose. We are not the first authors to look into this issue. For example, Friedman and his coauthors suggested using small steps [15, 14]. In fact, they argued that the smaller the step size, the better. They performed a number of empirical studies to support this claim. Therefore we shall not re-investigate this issue here. Instead, we focus on a closely related implication of our analysis, which will be useful for the purpose of reporting experimental results in later sections.

Let $\bar{\alpha}_i$ be the step size taken by the boosting algorithm at the i-th iteration. Our analysis characterizes the convergence behavior of boosting after the k-th step not by the number of iterations

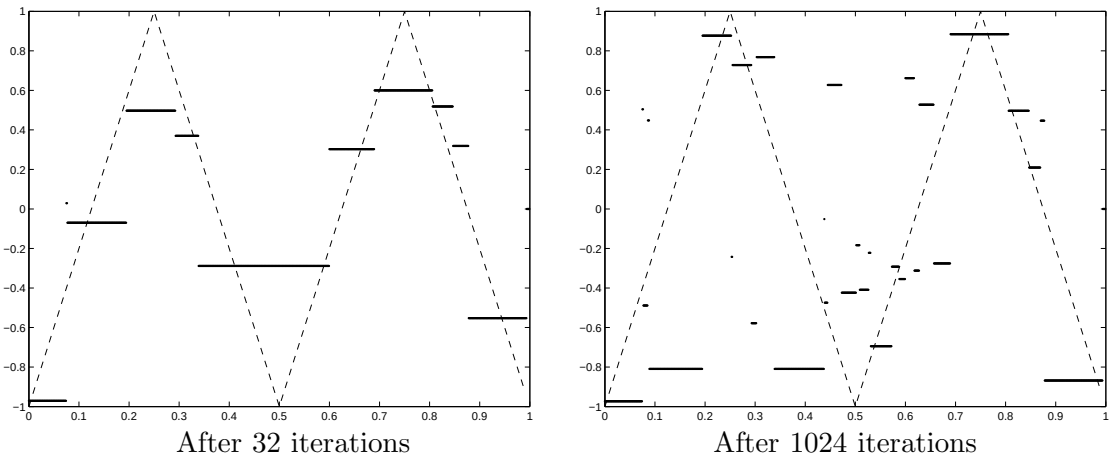

Figure 2: Graph of boosting estimator after $k = 32, 1024$ iterations

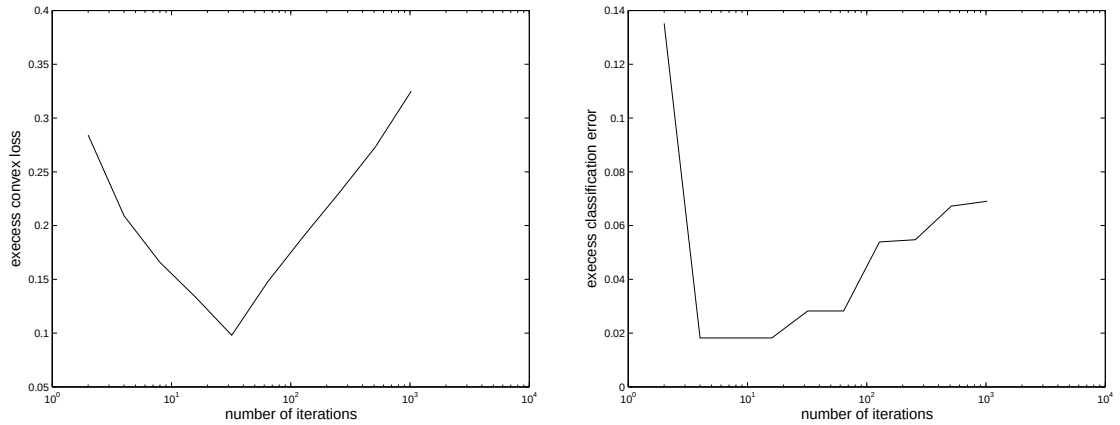
k itself, but rather by the quantity $s_k = \sum_{i \le k} h_i$ in (10), as long as $\bar{\alpha}_i \le h_i \in \Lambda_i$. Although our theorems are stated with the quantity $\sum_{i \le k} h_i$, instead of $\sum_{i \le k} \bar{\alpha}_i$, it does suggest that in order to compare the behavior of boosting under different configurations, it is more natural to use the quantity $\sum_{i \le k} \bar{\alpha}_i$ (which we shall call *total stepsize* throughout later experiments) as a measure of stopping point rather than the actually number of boosting iterations. This concept of total stepsize also appeared in [17, 18].

Figure 5 shows the predicative performance of boosting versus the total stepsize. We use 100 training examples, with the target conditional probability of complexity $d = 3$. The unrestricted step size method uses exact optimization. Note that for the least squares loss, as explained in Appendix C, the resulting step sizes will still satisfy our consistency condition of $\sum_{i \le k} \bar{\alpha}_i^2 < \infty$. The restricted step size scheme with stepsize $\le h$ employs a constant stepsize restriction of $\hat{\alpha}_i \le h$. This experiment shows that the behavior of these different boosting methods behave quite similarly when we measure the performance not by the number of boosting iterations, but instead by the total stepsize. This observation justifies our theoretical analysis, which uses quantities closely related to the total stepsize to characterize the convergence behavior of boosting methods. Based on this result, in the next few experiments, we shall use the total stepsize (instead of the number of boosting iterations) to compare boosting methods under different configurations.

6.4 The effect of sample size on early-stopping

An interesting issue for boosting with early-stopping is how its predicative behavior changes when the number of samples increases. Although our analysis does not offer a quantitative characterization, it implies that we should stop later (and the allowable stopping range becomes wider) when sample size increases. This essentially suggests that the optimal stopping point in the boost-



Excessive convex loss Excessive classification error

Figure 3: Predictive performance of boosting as a function of boosting iterations

ing predicative performance curve will increase as the sample size increases, and the curve itself becomes flatter. It follows that when the sample size is relatively large, we should run boosting algorithms for a longer time, and it is less necessary to do aggressive early-stopping.

The above qualitative characterization of boosting predicative curve also has important practical consequences. We believe this may be one reason why in many practical problems, it is very difficult for boosting to overfit, and practitioners often observe that the performance of boosting keeps improving as the number of boosting iterations increases.

Figure 6 shows the effect of sample size on the behavior of boosting method. Since our theoretical analysis applies directly to the convergence of convex loss (the convergence of classification error is followed implicitly as a consequence of convex loss convergence), the phenomenon described above is more apparent for excessive convex loss curves. The effect on classification error is less obvious, which suggests there is a discrepancy between classification error performance and convex loss minimization performance.

6.5 Early stopping and consistency

In this experiment, we demonstrate that as sample size increases, boosting with early-stopping leads to a consistent estimator with its error rate approaching the optimal Bayes error. Clearly, it is not possible to prove consistency experimentally, which requires running a sample size of ∞. We can only use a finitely number of samples to demonstrate a clear trend that the predicative performance of boosting with early-stopping converges to the Bayes error when the sample size increases. Another main focus of this experiment is to compare the performance of different early-stopping strategies.

Theoretical results in this paper suggest that for least squares loss, we can achieve consistency as

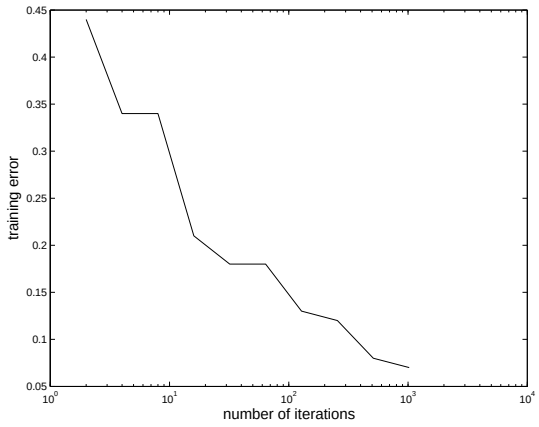


Figure 4: Training error

long as we stop at total stepsize at approximately m^ρ with $\rho < 1/4$, where m is the sample size. We call such an early-stopping strategy the *ρ-strategy*. Since our theoretical estimate is conservative, we examine the ρ-strategy both for $\rho = 1/6$ and for $\rho = 1/4$. Instead of the theoretically motivated (and suboptimal) ρ-strategy, in practice one can use cross-validation to determine the stopping-point. We use a sample size of one-third the training data to estimate the optimal stopping total stepsize which minimizes the classification error on the validation set, and then use the training data to compute a boosting estimator which stops at this cross-validation determined total stepsize. This strategy is referred to as the *cross-validation* strategy. Figure 7 compares the three early-stopping strategies mentioned above. It may not be very surprising to see that the cross-validation based method is more reliable. The ρ-strategies, although perform less well, also demonstrate a trend of convergence to consistency. We have also noticed that the cross-validation scheme stops later than the ρ-strategies, implying that our theoretical results impose more restrictive conditions than necessary.

It is also interesting to see how well cross-validation finds the optimal stopping point. In Figure 8, we compare the cross-validation strategy with two oracle strategies which are not implementable: one selects the optimal stopping point which minimizes the true classification error (which we refer to as *optimal error*), and the other selects the optimal stopping point which minimizes the true convex loss (which we refer to as *optimal convex risk*). These two methods can be regarded as ideal theoretical stopping points for boosting methods. The experiment shows that cross-validation performs quite well at large sample sizes.

In the log coordinate space, the convergence curve of boosting with the cross-validation stopping criterion is approximately a straight-line, which implies that the excess errors decrease as a power of the sample size. By extrapolating this finding, it is reasonable for us to believe that boosting with early-stopping converges to the Bayes error in the limit, which verifies the consistency. The two ρ stopping rules, even though showing much slower linear convergence trend, also lead to consistency.

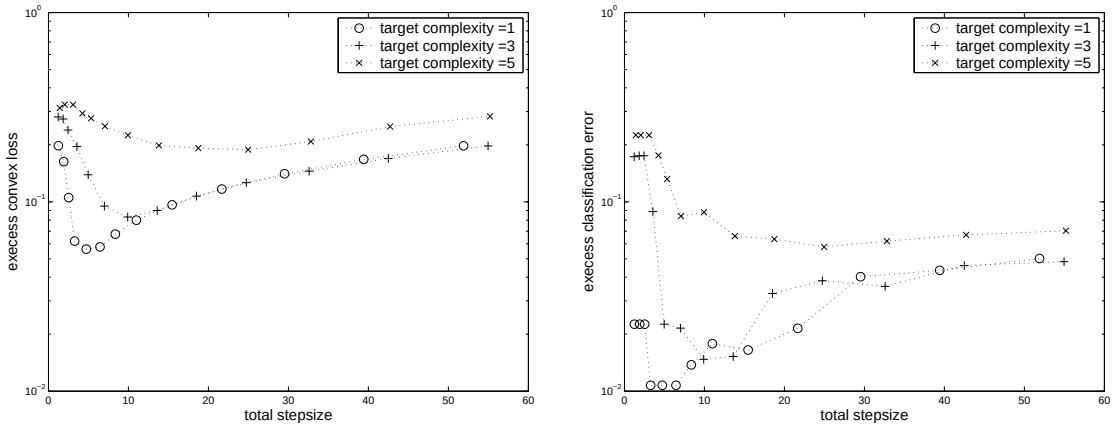
6.6 The effect of target function complexity on early-stopping

Although we know that boosting with an appropriate early-stopping strategy leads to a consistent estimator in the large sample limit, the rate of convergence depends on the complexity of target function (see Section 5.3). In our analysis, the complexity can be measured by the 1-norm of the target function. For target functions considered here, it is not very difficult to show that in order to approximate it to an accuracy within ϵ, it is only necessary to use a combination of our decision stumps with 1-norm Cd/ϵ. In this formula, C is a constant, and d is the complexity of the target function.

Our analysis suggests that the convergence behavior of boosting with early-stopping depends on how easy it is to approximate the target function using a combination of basis functions with small 1-norm. A target with $d = u$ is u-times as difficult to approximate as a target with $d = 1$. Therefore the optimal stopping point, measured by the total stepsize, should accordingly increase as d increases. Moreover, the predicative performance becomes worse. Figure 9 illustrates this phenomenon with $d = 1, 3, 9$ at the sample size of 300. Notice again that since our analysis applies to the convex risk, this phenomenon is much more apparent for the excessive convex loss performance than the excessive classification error performance. Clearly this again shows that although by minimizing a convex loss, we indirectly minimizes the classification error, these two quantities do not behave identically.



Excessive convex loss Excessive classification error

Figure 9: The effect of target function complexity

7 Conclusion

In this paper, we studied a general version of boosting procedure given in Algorithm 2.1. The numerical convergence behavior of this algorithm is studied using the so-called averaging technique,

which was previously used to analyze greedy algorithms for optimization problems defined in the convex hull of a set of basis functions. We derived an estimate of the numerical convergence speed and established conditions that ensure the convergence of Algorithm 2.1. Our results generalize those in previous studies such as the matching pursuit analysis in [29] and the convergence analysis of Adaboost by Breiman [9].

Furthermore, we studied the learning complexity of boosting algorithms based on the Rademacher complexity of the basis functions. Together with the numerical convergence analysis, we established a general early-stopping criterion for greedy boosting procedures for various loss functions that guarantees the consistency of the obtained estimator in the large sample limit. For specific choices of stepsizes and sample independent stopping criteria, we are also able to establish bounds on the statistical rate of convergence. We would like to mention that the learning complexity analysis given in this paper is rather crude. Consequently, the required conditions in our consistency strategy may be more restrictive than one actually needs.

A number of experiments were presented to study various aspects of boosting with early-stopping. We specifically focused on issues that have not been covered by previous studies. These experiments show that various quantities and concepts revealed by our theoretical analysis lead to observable consequences. This suggests that our theory can lead to useful insights into practical applications of boosting algorithms.

A Loss function examples

We list commonly used loss functions that satisfy Assumption 3.1. They show that for a typical boosting loss function ϕ, there exists a constant M such that $\sup_a M(a) \leq M$. All loss functions considered are convex.

A.1 Logistic Regression

This is a traditional loss function used in statistics, which is given by (in natural log here)

$$\phi(f, y) = \ln(1 + \exp(-fy)), \quad \psi(u) = u.$$

We assume that the basis functions satisfy the condition

$$\sup_{g \in S, x} |g(x)| \leq 1, \qquad y = \pm 1.$$

It can be verified that $A(f)$ is convex differentiable. We also have

$$A''_{f,g}(0) = E_{X,Y} \frac{g(X)^2 Y^2}{(1 + \exp(f(X)Y))(1 + \exp(-f(X)Y))} \leq 1/4.$$

A.2 Exponential Loss

This loss function is used in the AdaBoost algorithm, which is the original boosting procedure for classification problems. It is given by

$$\phi(f, y) = \exp(-fy), \quad \psi(u) = \ln u.$$

Again we assume that the basis functions satisfy the condition

$$\sup_{g \in S, x} |g(x)| \leq 1, \qquad y = \pm 1.$$

In this case, it is also not difficult to verify that $A(f)$ is convex differentiable. Hence we also have

$$A''_{f,g}(0) = \frac{E_{X,Y} g(X)^2 Y^2 \exp(-f(X)Y)}{E_{X,Y} \exp(-f(X)Y)} - \frac{[E_{X,Y} g(X) Y \exp(-f(X)Y)]^2}{[E_{X,Y} \exp(-f(X)Y)]^2} \leq 1.$$

A.3 Least Squares

The least squares formulation has been widely studied in regression, but can also be applied to classification problems[10, 11, 14, 30]. Greedy boosting-like procedure for least squares was firstly proposed in the signal processing community, where it was called *matching pursuit* [29]. The loss function is given by

$$\phi(f, y) = \frac{1}{2}(f - y)^2, \quad \psi(u) = u.$$

We impose the following weaker condition on the basis functions

$$\sup_{g \in S} E_X g(X)^2 \leq 1, \quad E_Y Y^2 < \infty.$$

It is clear that $A(f)$ is convex differentiable, and the second derivative is bounded as

$$A''_{f,g}(0) = E_X g(X)^2 \leq 1.$$

A.4 Modified Least Squares

For classification problems, we may consider the following modified version of the least squares loss which has a better approximation property [38]:

$$\phi(f, y) = \frac{1}{2} \max(1 - fy, 0)^2, \quad \psi(u) = u.$$

Since this loss is for classification problems, we impose the following condition

$$\sup_{g \in S} E_X g(X)^2 \leq 1, \quad y = \pm 1.$$

It is clear that $A(f)$ is convex differentiable, and we have the following bound for the second derivative

$$A''_{f,g}(0) \leq E_X g(X)^2 \leq 1.$$

A.5 p-norm boosting

p-norm loss can be interesting both for regression and classification. In this paper we will only consider the case with $p \geq 2$:

$$\phi(f,y) = |f-y|^p, \quad \psi(u) = \frac{1}{2(p-1)} u^{2/p}.$$

We impose the following condition

$$\sup_{g \in S} E_X |g(X)|^p \leq 1, \quad E_Y |Y|^p < \infty.$$

Now let $u = E_{X,Y}|f(X) + hg(X) - Y|^p$, we have

$$A'_{f,g}(h) = \frac{1}{p-1} u^{(2-p)/p} E_{X,Y} g(X) \mathrm{sign}(f(X) + hg(X) - Y)|f(X) + hg(X) - Y|^{p-1}.$$

Therefore the second derivative can be bounded as:

$$\begin{aligned}
A''_{f,g}(h) =& u^{(2-p)/p} E_{X,Y} g(X)^2 |f(X) + hg(X) - Y|^{p-2} \\
& - \frac{p-2}{p-1} u^{(2-2p)/p} [E_{X,Y} g(X) \mathrm{sign}(f(X) + hg(X) - Y)|f(X) + hg(X) - Y|^{p-1}]^2 \\
\leq & u^{(2-p)/p} E_{X,Y} g(X)^2 |f(X) + hg(X) - Y|^{p-2} \\
\leq & u^{(2-p)/p} \, E_{X,Y}^{2/p} |g(X)|^p \, E_{X,Y}^{(p-2)/p} |f(X) + hg(X) - Y|^p \\
= & E_{X,Y}^{2/p} |g(X)|^p \leq 1,
\end{aligned}$$

where the second inequality follows from Hölder's inequality with the duality pair $(p/2, p/(p-2))$.

Remark A.1 *Similar to the least squares case, we can define the modified p-norm loss for classification problems. Although the case $p \in (1,2)$ can be handled by the proof technique used in this paper, it requires a modified analysis since in this case the corresponding loss function is not second order differentiable at zero. See related discussions in [37]. Note that the hinge loss used in Support Vector Machines cannot be handled directly with our current technique since its first-order derivative is discontinuous. However, one may approximate the hinge loss with a continuously differentiable function, which can then be analyzed.*

B Numerical Convergence Proofs

This section contains the two proofs from the numerical convergence analysis section (Section 4.1).

Proof of One-step Analysis or Lemma 4.1:

Given an arbitrary fixed reference function $\bar{f} \in \text{span}(S)$ with the representation

$$\bar{f} = \sum_j \bar{w}^j \bar{f}_j, \quad \bar{f}_j \in S, \tag{22}$$

we would like to compare $A(f_k)$ to $A(\bar{f})$. Since $\bar{f}$ is arbitrary, we use such a comparison to obtain a bound on the numerical convergence rate.

Given any finite subset $S' \subset S$ such that $S' \supset \{\bar{f}_j\}$, we can represent $\bar{f}$ minimally as

$$\bar{f} = \sum_{g \in S'} \bar{w}^g_{S'} g,$$

where $\bar{w}^g_{S'} = \bar{w}^j$ when $g = \bar{f}_j$ for some j, and $\bar{w}^g_{S'} = 0$ when $g \notin \{\bar{f}_j\}$. A quantity that will appear in our analysis is $\|\bar{w}_{S'}\|_1 = \sum_{g \in S'} |\bar{w}^g_{S'}|$. Since $\|\bar{w}_{S'}\|_1 = \|\bar{w}\|_1$, without any confusion, we will still denote $\bar{w}_{S'}$ by $\bar{w}$ with the convention that $\bar{w}^g = 0$ for all $g \notin \{\bar{f}_j\}$.

Given this reference function $\bar{f}$, let us consider a representation of f_k as a linear combination of a finite number of functions $S_k \subset S$, where $S_k \supset \{\bar{f}_j\}$ to be chosen later. That is, with g indexing an arbitrary function in S_k, we expand f_k in terms of f^g_k's which are members of S_k with coefficients β^g_k:

$$f_k = \sum_{g \in S_k} \beta^g_k f^g_k. \tag{23}$$

With this representation, we define

$$\Delta W_k = \|\bar{w} - \beta_k\|_1 = \sum_{g \in S_k} |\bar{w}^g - \beta^g_k|.$$

Recall that in the statement of the lemma, the convergence bounds are in terms of $\|\bar{w}\|_1$ and a sequence of non-decreasing numbers s_k, which satisfies the following condition:

$$s_k = \|f_0\|_1 + \sum_{i=0}^{k-1} h_i, \qquad |\bar{\alpha}_k| \le h_k \in \Lambda_k,$$

where h_k can be any real number that satisfies the above inequality, which may or may not depend on the actually step size $\bar{\alpha}_k$ computed by the boosting algorithm.

Using the definition of 1-norm for $\bar{f}$ and since $f_0 \in \text{span}(S)$, it is clear that $\forall \epsilon > 0$, we can choose a finite subset $S_k \subset S$, vector β_k and vector $\bar{w}$ such that

$$\|\beta_k\|_1 = \sum_{g \in S_k} |\beta^g_k| \le s_k + \epsilon/2, \qquad \|\bar{w}\|_1 \le \|\bar{f}\|_1 + \epsilon/2.$$

It follows that with appropriate representation, the following inequality holds for all $\epsilon > 0$:

$$\Delta W_k \le s_k + \|\bar{f}\|_1 + \epsilon. \tag{24}$$

We now proceed to show that even in the worse case, the value $A(f_{k+1}) - A(\bar{f})$ decreases from $A(f_k) - A(\bar{f})$ by a reasonable quantity.

The basic idea is to upper bound the minimum of a set of numbers by an appropriately chosen weighted average of these numbers. This proof technique, which we shall call "averaging method", was used in [20, 1, 25, 37] for analyses of greedy type algorithms.

For h_k that satisfies (10), the symmetry of Λ_k implies $h_k \mathrm{sign}(\bar{w}^g - \beta_k^g) \in \Lambda_k$. Therefore the approximate minimization step (3) implies that for all $g \in S_k$, we have

$$A(f_{k+1}) \leq A(f_k + h_k s^g g) + \epsilon_k, \qquad s^g = \mathrm{sign}(\bar{w}^g - \beta_k^g).$$

Now multiply the above inequality by $|\bar{w}^g - \beta_k^g|$, and sum over $g \in S_k$, we obtain

$$\Delta W_k (A(f_{k+1}) - \epsilon_k) \leq \sum_{g \in S_k} |\beta_k^g - \bar{w}^g| A(f_k + h_k s^g g) =: B(h_k). \tag{25}$$

We only need to upper bound $B(h_k)$, which in turn gives an upper bound on $A(f_{k+1})$.

We recall a simple but important property of a convex function that follows directly from the definition of convexity of $A(f)$ as a function of f: $\forall f_1, f_2$

$$A(f_2) \geq A(f_1) + \nabla A(f_1)^T (f_2 - f_1). \tag{26}$$

If $A(f_k) - A(\bar{f}) < 0$, then $\Delta A(f_k) = 0$. From $0 \in \Lambda_k$ and (3), we obtain

$$A(f_{k+1}) - A(\bar{f}) \leq A(f_k) - A(\bar{f}) + \epsilon_k \leq \bar{\epsilon}_k,$$

which implies (13). Hence the lemma holds in this case. Therefore in the following, we assume that $A(f_k) - A(\bar{f}) \geq 0$.

Using Taylor expansion, we can bound each term on the right hand side of (25) as:

$$A(f_k + h_k s^g g) \leq A(f_k) + h_k s^g \nabla A(f_k)^T g + \frac{h_k^2}{2} \sup_{\xi \in [0,1]} A''_{f_k, g}(\xi h_k s^g).$$

Since Assumption 3.1 implies that

$$\sup_{\xi \in [0,1]} A''_{f_k, g}(\xi h_k s^g) = \sup_{\xi \in [0,1]} A''_{f_k + \xi h_k, g}(0) \leq M(\|f_k\|_1 + h_k),$$

we have

$$A(f_k + h_k s^g g) \leq A(f_k) + h_k s^g \nabla A(f_k)^T g + \frac{h_k^2}{2} M(\|f_k\|_1 + h_k).$$

Taking a weighted average, we have:

$$\begin{aligned}
B(h_k) &= \sum_{g\in S_k} |\beta_k^g - \bar{w}^g| A(f_k + h_k s^g g) \\
&\le \sum_{g\in S_k} |\beta_k^g - \bar{w}^g| \left[A(f_k) + \nabla A(f_k)^T h_k s^g g + \frac{h_k^2}{2} M(\|f_k\|_1 + h_k) \right] \\
&= \Delta W_k A(f_k) + h_k \nabla A(f_k)^T (\bar{f} - f_k) + \frac{h_k^2}{2} \Delta W_k M(\|f_k\|_1 + h_k) \\
&\le \Delta W_k A(f_k) + h_k [A(\bar{f}) - A(f_k)] + \frac{h_k^2}{2} \Delta W_k M(\|f_k\|_1 + h_k).
\end{aligned}$$

The last inequality follows from (26). Now using (25) and the bound $\|f_k\|_1 + h_k \le s_{k+1}$, we obtain

$$(A(f_{k+1}) - A(\bar{f})) - \epsilon_k \le \left(1 - \frac{h_k}{\Delta W_k}\right) (A(f_k) - A(\bar{f})) + \frac{h_k^2}{2} M(s_{k+1}).$$

Now replace ΔW_k by the right hand side of (24) with $\epsilon \to 0$, we obtain the lemma. □

Proof of the multistep analysis or Lemma 4.2:
Note that $\forall a \ge 0$,

$$\begin{aligned}
\prod_{\ell=j}^{k} \left(1 - \frac{h_\ell}{s_\ell + a}\right) &= \exp\left(\sum_{\ell=j}^{k} \ln(1 - \frac{s_{\ell+1} - s_\ell}{s_\ell + a})\right) \\
&\le \exp\left(\sum_{\ell=j}^{k} -\frac{s_{\ell+1} - s_\ell}{s_\ell + a}\right) \le \exp\left(-\int_{s_j}^{s_{k+1}} \frac{1}{v + a} dv\right) \\
&= \frac{s_j + a}{s_{k+1} + a}.
\end{aligned}$$

By recursively applying (13), and using the above inequality, we obtain

$$\begin{aligned}
\Delta A(f_{k+1}) &\le \prod_{\ell=0}^{k} \left(1 - \frac{h_\ell}{s_\ell + \|\bar{f}\|_1}\right) \Delta A(f_0) + \sum_{j=0}^{k} \prod_{\ell=j+1}^{k} \left(1 - \frac{h_\ell}{s_\ell + \|\bar{f}\|_1}\right) \bar{\epsilon}_j \\
&\le \frac{s_0 + \|\bar{f}\|_1}{s_{k+1} + \|\bar{f}\|_1} \Delta A(f_0) + \sum_{j=0}^{k} \frac{s_{j+1} + \|\bar{f}\|_1}{s_{k+1} + \|\bar{f}\|_1} \bar{\epsilon}_j. \quad \square
\end{aligned}$$

C Discussion on Step-size

We have been deriving our results in the case of restricted step-size in which the crucial small step size condition is explicit. In this appendix, we investigate the case of unrestricted step-size under exact minimization, for which we show that the small step-size condition is actually implicit if the boosting algorithm converges. The implication is that the consistency (and rates of convergence)

results can be extended to such a case, although the analysis becomes more complicated.

Let $\Lambda_k = R$ for all k so that the size of $\bar{\alpha}_k$ in the boosting algorithm is unrestricted. For simplicity, we will only consider the case that $\sup_a M(a)$ is upper bounded by a constant M.

Interestingly enough, although the size of $\bar{\alpha}_k$ is not restricted in the boosting algorithm itself, for certain formulations the inequality $\sum_j \bar{\alpha}_j^2 < \infty$ still holds. Theorem 4.1 can then be applied to show the convergence of such boosting procedures. For convenience, we will impose the following additional assumption for the step size $\bar{\alpha}_k$ in Algorithm 2.1:

$$A(f_k + \bar{\alpha}_k \bar{g}_k) = \inf_{\alpha_k \in R} A(f_k + \alpha_k \bar{g}_k), \tag{27}$$

which means that given the selected basis function $\bar{g}_k$, the corresponding $\bar{\alpha}_k$ is chosen to be the exact minimizer.

Lemma C.1 *Assume that $\bar{\alpha}_k$ satisfies (27). If there exists a positive constant c such that*

$$\inf_k \inf_{\xi \in (0,1)} A''_{(1-\xi)f_k + \xi f_{k+1},\, \bar{g}_k}(0) \geq c,$$

then

$$\sum_{j=0}^{k} \bar{\alpha}_j^2 \leq 2c^{-1}[A(f_0) - A(f_{k+1})].$$

Proof. Since $\bar{\alpha}_k$ minimizes $A_{f_k,\bar{g}_k}(\alpha)$, $A'_{f_k,\bar{g}_k}(\bar{\alpha}_k) = 0$. Using Taylor expansion, we obtain

$$A_{f_k,\bar{g}_k}(0) = A_{f_k,\bar{g}_k}(\bar{\alpha}_k) + \frac{1}{2} A''_{f_k,\bar{g}_k}(\xi_k \bar{\alpha}_k)\bar{\alpha}_k^2,$$

where $\xi_k \in (0,1)$. That is, $A(f_k) = A(f_{k+1}) + \frac{1}{2} A''_{f_k,\bar{g}_k}(\xi_k \bar{\alpha}_k)\bar{\alpha}_k^2$. By assumption, we have $A''_{f_k,\bar{g}_k}(\xi_k \bar{\alpha}_k) \geq c$. It follows that, $\forall j \geq 0$, $\bar{\alpha}_j^2 \leq 2c^{-1}[A(f_j) - A(f_{j+1})]$. We can obtain the lemma by summing from $j = 0$ to k. □

By combining Lemma C.1 and Corollary 4.1, we obtain

Corollary C.1 *Assume that $\sup_a M(a) < +\infty$ and ϵ_j in (3) satisfies $\sum_{j=0}^{\infty} \epsilon_j < \infty$. Assume also that in Algorithm 2.1, we let $\Lambda_k = R$ and let $\bar{\alpha}_k$ satisfy (27). If*

$$\inf_k \inf_{\xi \in (0,1)} A''_{(1-\xi)f_k + \xi f_{k+1},\, \bar{g}_k}(0) > 0,$$

then

$$\lim_{k \to \infty} A(f_k) = \inf_{f \in \mathrm{span}(S)} A(f).$$

Proof. If $\lim_{k\to\infty} A(f_k) = -\infty$, then the conclusion is automatically true. Otherwise, Lemma C.1 implies that $\sum_{j=0}^{\infty} \bar{\alpha}_j^2 < \infty$. Now choose $h_j = |\bar{\alpha}_j| + 1/(j+1)$ in (10), we have $\sum_{j=0}^{\infty} h_j = \infty$, and $\sum_{j=0}^{\infty} h_j^2 < \infty$. The convergence now follows from Corollary 4.1. □

Least squares loss

The convergence of unrestricted step-size boosting using the least squares loss (matching pursuit) was studied in [29]. Since a scaling of the basis function does not change the algorithm, without loss of generality, we can assume that $E_X g(X)^2 = 1$ for all $g \in S$ (assume S does not contain function 0). In this case, it is easy to check that $\forall g \in S$:

$$A''_{f,g}(0) = E_X g(X)^2 = 1.$$

Therefore the conditions in Corollary C.1 are satisfied as long as $\sum_{j=0}^{\infty} \epsilon_j < \infty$. This shows that the matching pursuit procedure converges, that is,

$$\lim_{k\to\infty} A(f_k) = \inf_{f\in \mathrm{span}(S)} A(f).$$

We would like to point out that for matching pursuit, the inequality in (C.1) can be replaced by the following equality

$$\sum_{j=0}^{k} \bar{\alpha}_j^2 = 2[A(f_0) - A(f_{k+1})],$$

which was referred to as "energy conservation" in [29], and was used there to prove the convergence.

Exponential loss

The convergence behavior of boosting with the exponential loss was previously studied by Breiman [9] for ± 1-trees under the assumption $\inf_x P(Y = 1|x)P(Y = -1|x) > 0$. Using exact computation, Breiman obtained an equality similar to the matching pursuit energy conservation equation. As part of the convergence analysis, the equality was used to show $\sum_{j=0}^{\infty} \bar{\alpha}_j^2 < \infty$.

The following lemma shows that under a more general condition, the convergence of unrestricted boosting with exponential loss follows directly from Corollary C.1. This result extends that of [9], but the condition still constraints the class of measures that generate the joint distribution of (X, Y).

Lemma C.2 *Assume that*

$$\inf_{g\in S} E_X |g(X)| \sqrt{P(Y = 1|X)P(Y = -1|X)} > 0.$$

If $\bar{\alpha}_k$ *satisfies (27), then* $\inf_k \inf_{\xi\in(0,1)} A''_{(1-\xi)f_k+\xi f_{k+1},\, \bar{g}_k}(0) > 0$. *Hence* $\sum_j \bar{\alpha}_j^2 < \infty$.

Proof. For notation simplicity, we let $q_{X,Y} = \exp(-f(X)Y)$. Recall that the direct computation of

$A''_{f,g}(0)$ in Section A.2 yields

$$
\begin{aligned}
&[E_{X,Y} q_{X,Y}]^2 \, A''_{f,g}(0) \\
=&[E_{X,Y} g(X)^2 q_{X,Y}] \, [E_{X,Y} q_{X,Y}] - [E_{X,Y} g(X) Y q_{X,Y}]^2 \\
=&[E_X g(X)^2 E_{Y|X} q_{X,Y}] \, [E_X E_{Y|X} q_{X,Y}] - [E_X g(X) E_{Y|X} Y q_{X,Y}]^2 \\
\geq&[E_X g(X)^2 E_{Y|X} q_{X,Y}] \, [E_X E_{Y|X} q_{X,Y}] - [E_X g(X)^2 |E_{Y|X} Y q_{X,Y}|] \, [E_X |E_{Y|X} Y q_{X,Y}|] \\
\geq&[E_X g(X)^2 E_Y q_{X,Y}] \, E_X [E_{Y|X} q_{X,Y} - |E_{Y|X} Y q_{X,Y}|] \\
\geq& \left[E_X |g(X)| \sqrt{E_Y q_{X,Y} (E_{Y|X} q_{X,Y} - |E_{Y|X} Y q_{X,Y}|)} \right]^2 \\
\geq& \left[E_X |g(X)| \sqrt{2P(Y=1|X) P(Y=-1|X)} \right]^2 .
\end{aligned}
$$

The first and the third inequalities follow from Cauchy-Schwartz, and the last inequality used the fact that $(a+b)((a+b)-|a-b|) \geq 2ab$. Now observe that $E_{X,Y} q_{X,Y} = \exp(A(f))$. The exact minimization (27) implies that $A(f_k) \leq A(f_0)$ for all $k \geq 0$. Therefore using Jensen's inequality we know that $\forall \xi \in (0,1), A((1-\xi) f_k + \xi f_{k+1}) \leq A(f_0)$. This implies the desired inequality:

$$
A''_{(1-\xi) f_k + \xi f_{k+1}, \, \bar{g}_k}(0) \geq \exp(-2A(f_0)) \left[E_X |\bar{g}_k(X)| \sqrt{2P(Y=1|X) P(Y=-1|X)} \right]^2 .
$$

□

Although unrestricted step-size boosting procedures can be successful in certain cases, for general problems, we are unable to prove convergence. In such cases, the crucial condition of $\sum_{j=0}^{\infty} \bar{\alpha}_j^2 < \infty$, as required in the proof of Corollary C.1, can be violated. Although we don't have concrete examples at this point, we believe boosting may fail to convergence when this condition is violated.

For example, for logistic regression, we are unable to prove a result similar to Lemma C.2. The difficulty is caused by the near-linear behavior of the loss function toward negative infinity. This means that the second derivative is so small that we may take an extremely large step size when $\bar{\alpha}_j$ is exactly minimized.

Intuitively, the difficulty associated with large $\bar{\alpha}_j$ is due to the potential problem of large oscillation in that a greedy-step may search for a sub-optimal direction, which needs to be corrected later on. If a large step is taken toward the sub-optimal direction, then many more additional steps have to be taken to correct the mistake. If the additional steps are also large, then we may over correct and go to some other sub-optimal directions. In general it becomes difficult to keep track of the overall effect.

D The relationship of Adaboost and L_1-margin Maximization

Given a real-valued classification function $p(x)$, we consider the following discrete prediction rule:

$$y = \begin{cases} 1 & \text{if } p(x) \geq 0, \\ -1 & \text{if } p(x) < 0. \end{cases} \tag{28}$$

Its classification error (for simplicity, we ignore the point $p(x) = 0$, which is assumed to occur rarely) is given by

$$L_\gamma(p(x), y) = \begin{cases} 1 & \text{if } p(x)y \leq \gamma, \\ 0 & \text{if } p(x)y > \gamma \end{cases}$$

with $\gamma = 0$. In general, we may consider $\gamma \geq 0$ and the parameter $\gamma \geq 0$ is often referred to as margin, and we shall call the corresponding error function L_γ margin error.

In [33] the authors proved that under appropriate assumptions on the base learner, the expected margin error L_γ with a positive margin $\gamma > 0$ also decreases exponentially. It follows that regularity assumptions of weak learning for Adaboost imply the following margin condition: $\exists \gamma > 0$ such that $\inf_{f \in \text{span}(S), \|f\|_1 = 1} L_\gamma(f, y) = 0$, which in turn implies the following inequality: $\forall s > 0$,

$$\inf_{f \in \text{span}(S), \|f\|_1 = 1} E_{X,Y} \exp(-sf(X)Y) \leq \exp(-\gamma s). \tag{29}$$

We now show that under (29), the expected margin errors (with small margin) from Algorithm 2.1 may decrease exponentially. A similar analysis was given in [37]. However, the boosting procedure considered there was modified so that the estimator always stays in a scaled convex hull of the basis functions. This restriction is removed in the current analysis.

$$f_0 = 0, \quad \sup \Lambda_k \leq h_k, \quad \epsilon_k \leq h_k^2/2.$$

Note that this implies that $\bar{\epsilon}_k \leq h_k^2$ for all k.

Now applying (15) with $\bar{f} = sf$ for any $s > 0$ and let f approach the minimum in (29), we obtain (recall $\|f\|_1 = 1$)

$$A(f_k) \leq -s\gamma \frac{s_k}{s_k + s} + \sum_{j=1}^{k} \frac{s_j + s}{s_k + s} \bar{\epsilon}_{j-1} \leq -s\gamma \frac{s_k}{s_k + s} + \sum_{j=0}^{k-1} h_j^2.$$

Now let $s \to \infty$, we have

$$A(f_k) \leq -\gamma s_k + \sum_{j=0}^{k-1} h_j^2.$$

Assume we pick a constant $h < \gamma$ and let $h_k = h$, then

$$E_{X,Y} \exp(-f_k(X)Y) \leq \exp(-kh(\gamma - h)), \tag{30}$$

which implies that the margin error decreases exponentially for all margin less than $\gamma - h$. To see this, consider $\gamma' < \gamma - h$. Since $\|f_k\|_1 \leq kh$, we have from (30)

$$L_{\gamma'}(f_k(x)/\|f_k\|_1, y) \leq P(f_k(X)Y \leq kh\gamma') \leq E_{X,Y} \exp(-f_k(X)Y + kh\gamma') \leq \exp(-kh(\gamma - h - \gamma')).$$

Therefore

$$\lim_{k\to\infty} L_{\gamma'}(f_k(x)/\|f_k\|_1, y) = 0.$$

This implies that as $h \to 0$, $f_k(x)/\|f_k\|_1$ achieves a margin that is within h of the maximum possible. Therefore when $h \to$ and $k \to \infty$, $f_k(x)/\|f_k\|_1$ approaches a maximum margin separator.

Note that in this particular case we allow a small step size ($h < \gamma$), which violates the condition $\sum_k h_k^2 < \infty$ imposed for the boosting algorithm to converge. However, this condition that prevents large oscillation to occur is only a sufficient condition to guarantee convergence. For specific problems, especially when $\inf_{f\in \mathrm{span}(S)} A(f) = -\infty$, it is still possible to achieve convergence even if the condition is violated.
